In this country children are now very generally vaccinated, owing to the requirements in this respect which obtain in the various schools. But during adult life there occurs only an occasional compulsory vaccination, and most adults submit to revaccination merely when a smallpox scare arises in their immediate vicinity. Therefore, in the United States it is mostly during adult life that individuals are subject to the baneful effects of the disease under discussion. As a matter of fact our adult population, for the most part, even though they have been vaccinated in childhood may be deemed (through the loss of immunity) practically unvaccinated. Germany is unique in this respect. There the strict regulations prescribe that not only primary vaccination in infancy must take place, but also revaccination in adult life; and, as a result, that country is now almost entirely free from smallpox, and its hospitals provide merely nominal accommodations for the same. Indeed, so infrequently is it met with that Dr. Baumler, of Freiburg, remarks in a recent paper that there has been no opportunity to observe the disease in his clinic (one of large clientele) for the previous nine years. It seems customary in the foreign countries to be much more rigorous in the matter of compulsory vaccination among adults than it is in our own, and their authorities look to it that not only is vaccination performed in young children, but that a follow-up method is observed; and people reaching the adult stage find they must submit to a revaccination as a protection to themselves and to the communities of which they are members. As an example of the indifference of the Anglo-Saxon race generally in the matter of revaccination, one may point to the fact that in an epidemic in Canada occurring lately, of fifty-eight patients who were stricken with smallpox, every one had been born either in the British Isles or Canada, or in the United States; and either had not been vaccinated at all or had not been revaccinated.

One of the arguments which the antivaccinationists have always used is to the effect that even if a person should be vaccinated this fact does not really prevent his acquiring smallpox. What these obsessionists forget, or perhaps intentionally overlook, is that, although this may be true, yet there is a striking difference in the possible intensity of the disease in the vaccinated and in the unvaccinated. Dr. Hanna of Liverpool has recently emphasized this point by the exhibition of a remarkable series of actual photographs in which the obvious loathsomeness and the hideousness of the infection in those who had not been vaccinated were contrasted with the apparent mildness of the eruption in the cases of those who had received the benefits of vaccination.

The opponents of this procedure practically affirm that the medical profession for years has bolstered up the statistics in smallpox hospitals and in other places where there have been numbers of cases, and by juggling the records has made the results appear to be falsely favorable to vaccination. Puerile and

contemptible though such statements are, they have been sufficient, with the assistance of other inanities, to cause a rallying to their flag of many thoughtless people who, misguided in the adoption of their premises, have from time to time violently and vehemently given vent to their opposition to vaccination.

Medical history is replete with incidents which might refute their claims. One of the strongest offsets to their vaporings has been demonstrated lately by Dr. Hanna. He has carefully analyzed a series of undoubted cases of smallpox, some 1,163 in number. The cold facts are these:

That among 943 patients who had happened to be vaccinated in infancy there were 28 deaths, or about 2 per cent. mortality. On the other hand, of 220 patients who had not received vaccination, there was a percentage of deaths of about 27.2, showing a rough ratio of about ten times greater mortality among the unvaccinated.

Another argument which the antis are fond of using is that possible blood poisoning may result as a sequela of the operation. In this they do have a certain basic argument of truth, for given an existing abrasion of the skin there is always present the possibility of a septic infection. However, with our present day knowledge of aseptic technique, and with the observance of due surgical carefulness, this danger has been reduced, we may truly say, to a minimum.

In fact, almost all cases of septic infections following vaccinations may be attributed to neglect in the after-care of the vaccinated lesion on the part of the patient or, in the cases of children, to the carelessness of those whose duty it is to look after them.

As to the contamination of vaccine during its preparation in the various commercial laboratories, we know that such an accident is rare, considering the enormous amount of vaccine used every year. The laboratories are under the strict surveillance of the United States government; frequent tests are made to determine the purity of the products; analyses often are made of vaccine bought in the open market; a special license is required before manufacture is allowed; and in a word, every precaution is used that the virus may be surely made free from extraneous substances of a harmful nature.

Many fallacious ideas have been held as to the injurious effects which may follow vaccination. One of the old-fashioned views was that a child when subjected to the inoculation of the lymph might forever afterward wear the expression of a cow. Almost all diseases and abnormalities from ingrowing toenails to baldness have been laid at the door of vaccination and ascribed to its evil and baneful effects.

It is a surprising fact that many people to-day still believe that vaccination as now performed is but a modification of the old arm-to-arm method; and it is possible that the inherent fear of contracting syphilis which exists in most persons forms the basis for much of the active opposition to vaccination. Of course the fact that calf-lymph is now used, and, moreover, the pregnant fact that calves are not susceptible to syphilis render absurd any such fear.

As to the lesion of vaccination itself, in the United States army a perfect scar is considered to be about one-half inch in diameter and to be free from the hard scar indicative of other infections.

Army surgeons are persistent in following up a "non-take" in a recruit who shows no scar, and vaccination is repeated every two weeks until successful. In the case of reenlistment, the only excuses from vaccination are (1) that the recruit has had smallpox, and (2) that there is undoubted evidence of two "successful takes."

The question has been often debated, "What in reality is smallpox?" Dr. Ashburn, in a recent monograph, has made an attempt to define it. He gives as an answer which he says defies any theoretical or practical criticism that "smallpox is due to a dual and divisible virus, one part of which causes vaccinia and the specific smallpox eruption, the other part being necessary for the production of the contagious, generalized, mortal disease, with a distinct preeruptive stage and initial rashes." Further, he states, "vaccinia therefore protects against the pox stage of smallpox rather than against the whole disease."

In concluding his remarks the writer wishes to quote part of a conversation which a physician related recently. It was in reference to the possible dangers from vaccination. A patient of his had become a doubting Thomas—was on the fence, so to speak—and had interviewed the doctor concerning the matter. The latter explained that of course there was a remote danger of infection. But he added: "Every year there are a certain number of people who suffer from sunstroke; therefore let's put the sun out of business."

CONTINUOUS TRANSFUSION; THE PRODUCTION OF IMMUNITY. AN EXPERIMENTAL STUDY.

By ALFRED KAHN, M.D.,

NEW YORK.

(From the Laboratory of Experimental Surgery, Bellevue Medical School.)

DIRECT transfusion of blood has been known for centuries, but its successful practice dates only from a comparatively recent time, this being due to approved technique and invention. Direct transfusion is the transference of blood from one subject to another. Continuous transfusion is not only the transfusion of blood from one subject to another but transfusion of blood from a second subject back to a first, the blood vessels being so arranged that there is a continual circulation back and forth—a swapping of the blood. Continuous transfusion was not to my knowledge mentioned in the history of medicine until October, 1912, and then in a theoretical article which was published by the author only in synopsis.

These experiments were done: First, in an endeavor to develop this method; second, to put the method to some practical use—hence the animals were infected in various ways and then afterward an endeavor made to immunize them.

Experiments.—Developing of technique: In experiments 1 and 2 animals were not infected; the vessels were merely joined for a continuous transfusion. In the first case, dog 76 died under the anesthetic. In the second experiment, a clot formed in one of the vessels, but we succeeded in getting a slight flow throughout the circuit before the clot formation.

In experiments 3 to 31, inclusive, the dogs were infected by opening the peritoneal cavity and inserting either (1) a small quantity of dust; (2) gauze

TABLE OF EXPERIMENTS

No. Experiment	Date	No. Dog	Object of Experiment	Nature of Experiment	Result	Remarks
1 Donor Inf.	1/10/14	76 75	Develop. Technique.	Crossed. Transfused.	No result.	Dog died under anesthetic.
2 Donor Inf.	1/17/14	86 87	Develop. Technique.	Crossed. Transfused.	No result.	Clot formed preventing transfusion.
3 Inf.	1/27/14	95	1st. To infected dog. 2nd. Transfusion continuously to produce immunity. Death before transfusion could be done.	Laparotomy incision. Peritoneal cavity opened. Dust placed in peritoneal cavity.	Dog died Jan. 30. Peritonitis.	Transfusion not attempted. Waited too long.
4 Inf.	1/31/14	98	Not transfused.		No result. Death anesthetic.	Not transfused.
5 Donor Inf.	1/31/14 2/3/14	99 102	1st. Infected dog. 2nd. Transfusion to produce immunity. Transfused 15 minutes.	Peritoneal cavity opened. Infected with dust. Wound sewed tight. No drainage.	Infected dog lived 12 days from date of infection.	Autopsy. Peritonetum clean. No pus. Death from neck wound. Dog (102) donor showed no involvement.
6 Donor Inf.	2/5/14 2/7/14	28 105	Same as previous experiment. Transfusion only partially successful.	Same as previous experiment.	No result.	Dog 28 (donor) lived months. Not effected by experiment. Dog 105 (inf.) died under anesthesia. Autopsy—general peritonitis; pus in peritoneal cavity.
7 Donor Inf.	2/12/14 2/10/14	113 29	Same as previous experiment. Transfused one hour.	Dust.	Infected dog lived 50 days when he was chloroformed.	Autopsy. Peritonetum clean. Donor O. K.
8 Donor Inf.	2/21/14 2/19/14	5 6	Same as previous experiment. Transfused one hour and five minutes.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	Excellent.	Infected dog killed and autopsied Feb. 26. Gauze walled off. No infection. Dog 5 remained well.
9 Donor Inf.	2/19/14 2/16/14	121 118	Same as previous experiment. Not transfused.	Peritoneal cavity opened infected with gauze covered with dust. Wound sewed tight. No drainage.	No result.	Dog died under anesthetic. Not transfused. General peritonitis pus.
10 Donor Inf.	2/28/14 2/23/14	136 128	Same as previous experiment. Transfused one hour and fifteen minutes.	Peritoneal cavity opened infected with gauze covered with dust. Wound sewed tight. No drainage.	Excellent.	Dog 136 remained well. Infected dog. Autopsied March 27. Pneumonia in right lung. Peritoneal clean. Dog lived 13 days after primary infection.
11 Inf.	3/2/14	137	Same as previous experiment. Not transfused.	Peritoneal cavity opened infected with gauze saturated with pus. Wound sewed tight. No drainage.	No result.	Dog died March 4. No transfusion done. Autopsy. General peritonitis. Gauze not walled off.
12 Inf.	3/5/14	143	Same as previous experiment. Not transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Animal died March 6. No transfusion. Autopsy. General peritonitis.
13 Inf.	3/13/14	154	Not transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Autopsy. General peritonitis.
14 Donor Inf.	3/19/14 3/18/14	165 162	Same as previous experiment. Transfused. Length of time not recorded.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	Excellent.	Infected dog recovered. The Donor remained well. Autopsy. April 9 Dog (162) gauze walled off. Peritoneum healthy. No pus. No infection.
15 Donor Inf.	3/21/14 3/20/14	170 168	Transfusion thirty minutes.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Dog died March 24. Autopsy General peritonitis.
16 Inf.	3/25/14	179	Not transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Autopsy. March 26. General peritonitis.
17 Donor Inf.	3/28/14 3/26/14	183 181	Same as previous experiment. Transfused 45 minutes.	Peritoneal cavity opened infected with gauze covered with dust. Wound sewed tight. No drainage.	Good.	Autopsy. April 8. No peritonitis. Dog (183) not affected.
18 Inf.	4/1/14		Not transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Dog died April 2 before transfusion could be done. Autopsy. Peritonitis.
19 Donor Inf.	4/11/14 4/10/14	211 209	Transfusion one hour.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No success.	Infected dog died April 14, four days after infection. Autopsy. General peritonitis. Gauze partially walled off. Abscess.

TABLE OF EXPERIMENTS

No. Experiment	Date	No. Dog	Object of Experiment	Nature of Experiment	Result	Remarks
20 Donor Inf.	4/16/14 4/15/14	216 215	Transfusion 45 minutes.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No success.	Infected dog (215) died April 18. Autopsy. Pus peritonitis. Gauze partially walled. Dog (216) not affected.
21 Inf.	4/21/14	220	Not transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Dog died April 22. No transfusion done. Autopsy. General peritonitis.
22 Inf.	4/24/14	221	Not transfused.	Peritoneal cavity opened infected with pus. Wound sewed tight. No drainage.	No result.	Dog died April 25. No transfusion. Autopsy. General peritonitis.
23 Donor Inf.	4/30/14 4/29/14	225	Transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	Excellent.	Autopsy. May 28, one month later. No peritonitis. Gauze walled off.
24 Donor Inf.	5/2/14 5/1/14	228 227	Transfusion one hour.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	Perfect result.	Autopsy. Sept. 9 peritoneum clean. Gauze walled off. Dog (228) not affected.
25 Donor Inf.	5/7/14 5/6/14	233 231	Transfusion one hour.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	Perfect.	Autopsy. Sept. 9. Peritoneum clean. Gauze walled off. Dog (233) lived on, showed no effect from transfusion.
26 Donor Inf.	5/9/14 5/8/14	236 234	Transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Dog died May 10th. General peritonitis. Gauze not walled off.
27 Donor Inf.	5/4/14 5/13/14	143 239	Transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	Excellent.	Autopsy. June 1. No peritonitis. Gauze walled off.
28 Inf.	5/18/14	246	Not transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Dog died May 20. No transfusion done. Autopsy. Peritonitis. Gauze not walled off.
29 Donor Inf.	5/21/14 5/20/14	254 250	Transfused.	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	Infected dog (250) died May 22. Autopsy. Localized peritonitis. Gauze partially walled.
30 Inf.	5/25/14	258	Not transfused	Peritoneal cavity opened infected with gauze covered with pus. Wound sewed tight. No drainage.	No result.	No transfusion done. Dog died May 27. Autopsy. Peritonitis. Gauze beginning to be localized.

saturated with pus; or (3) pure pus. The reason for infecting in this way was because the substances offered various strengths of infection. Where pure pus was used the dogs died within forty-eight hours, before transfusion could be done; the reaction with dust was slower; gauze saturated with pus presented a reaction between these two—between pure pus and dust.

Technique: In the table of experiments there are two dates to each experiment. On the first date the dogs to be infected were etherized, a laparotomy was done and the peritoneal cavity opened; infected material was inserted into cavity, and the wound was sewed tight, no drainage whatsoever. The second date is the date of transfusion. On this date the donor was selected, next shaved and etherized, and the external jugular exposed throughout the neck. The infected dog was similarly operated upon. The dogs were then turned head to head; the external jugular was cut in the middle in each dog and then joined for transfusion as follows: Upper end of vessel of dog A to lower end of vessel of dog B; the other two ends were similarly joined, then the clamps were removed, and blood was allowed to flow continuously throughout the circuit created between the two animals, from A to B and from B to A. In several of these experiments this continual

swapping of blood was kept up for over an hour; manifestly this could not be done with a direct transfusion. The advantages claimed for this method is that the transfusion can be kept up for an indefinite period between, if desired, several subjects, with a minimum loss of blood to each animal.

In none of these cases was there any attempt made to isolate a specific germ, nor were any blood tests made. It is thoroughly realized that the isolation of infecting germs would have made a more interesting paper, but a keen desire to report the continuous transfusion work prompts the experimenter to leave a more detailed study to a later period. The work done is doubtless gross, but it is only a beginning, a general survey of the subject, and later work will be done in more detail.

In dogs that were not transfused, death occurred in 24 to 48 hours, and in transfused dogs death was deferred from three to four days, or absolute recovery took place. All transfused dogs lived longer than the dogs that were not transfused.

Conclusion.—Continuous transfusion is experimentally successful between dogs for periods varying from one-half to three hours. The experimenter believes that he succeeded in raising the vital resistance in instances as related in these experiments. As to the production of immunity, he is in

doubt. In the words of one of my laboratory colleagues, the method doubtless has big possibilities, but a great deal more research is needed. I offer this as a preliminary report.

34 EAST FORTIETH STREET.

SOAP.*

By G. K. DICKINSON, M.D.,

JERSEY CITY, N. J.

So often does it happen that the commonplace, that which has become a customary practice, fails to receive the thoughtful attention deserved, while much more importance is placed upon that which is new and recently introduced into professional techniques. The time will probably never come when all will be satisfied with effective simplicity; not, at least, until it becomes a second habit. Even then the exploitation of some new medicament or method may obtain favor because of the strong attraction novelty possesses.

This applies with unusual appropriateness to soap. It has become such a customary thing to soap, lather, and rinse that no thought is given to the process, for the convention of cleanliness satisfies. But, perhaps, there may be more to soaping. There may be some other activity of importance, a study of which may lead to an enlightenment and more proper usage.

Anything is a soap which is a combination of oils with an alkali or alkaline earth. The commercial soaps are made of animal or vegetable oils combined with potash or soda. Soaps made in combination with the alkaline earths are insoluble and ineffective. The two types of soap on the market are: the soda, or hard soap, and the potash, or soft soap.

Not many years ago there were but few varieties of soap. These were imperfectly made, and, the process not being comprehended, the full effect was not obtained. To-day there are thousands of manufacturing, a large output, glaring advertisements, and a public dissemination of nicely made up material which attracts even the most ordinary person.

Although soap has been known for ages, it was not until 1813 that Chevreul¹ published the results of his scientific researches on the composition of fats and the process of soap making. He claimed that the cleansing action of soap was brought about by its decomposition in contact with water into fatty acids and an alkali, that the impurities were set free by the alkali, and that the fatty acids entangled them, all being removed with the lather.

According to Park's "Hygiene and Public Health," grease and dirt cannot be removed without the use of soap. The alkali of the soap combines with the grease and emulsifies it. Cheap soaps may contain an excess of alkali and produce irritation. The best results in saponification are obtained with soft water; that is, water free from lime or magnesia, for one grain of chalk will waste eight grains of soap. If a soap does not produce a lather, it is not efficacious.

Joseph, in "Prevention of Disease,"² says that if the fat on the surface of the skin is not emulsified, we cannot speak of cleanliness. The alkali dissolves the superficial horny layer of the skin.

But the interest of the sanitarian and the surgeon is not so much in ordinary cleanliness and cosmetic results as in the inhibition and destruction

of germ life. Not until the discovery of pathogenic germs could there be any thought as to the dual value of soap, but, since their discovery, particularly since the thorough researches of Koch,³ in 1881, there have been numerous experiments from different viewpoints in order to determine whether soap had any inhibiting action on any of the germs which induce disease. He studied the effect of potassium soaps on the development of the anthrax bacilli, and from the results of his observations concluded they had a very pronounced antiseptic power.

The following experiments are noted by Rodet⁴ in an article on the antiseptic value of soap:

In 1884 Wernich advised the use of solutions of potassium soap, but in mild strength.

Kuisl, in 1885, experimented with potassium soap on the control of the anthrax, typhoid, and cholera bacilli, but failed to find any antiseptic properties.

Di Mattei, in 1888, made studies in the efficacy of soap on the cholera vibrio, the typhoid bacillus, and the staphylococci.

In 1889 Kaupé made studies of the anthrax bacillus with ordinary soap.

Behring (1890) took forty varieties of soap, experimented with them, and came to the opinion that they possessed a real disinfectant power, but thought that the bactericidal effect was found in the alkali reaction alone. He was the first to denounce as useless the additions of antiseptics to soap.

Nijland, in 1893, used three kinds of soap—the soft potassium, the hard, and the medicated, and found the hard soap less antiseptic than the soft. Those to which phenic and salicylic acids had been added seemed to be diminished in power.

In 1893 Jolles experimented on numerous soaps of the potassium and sodium types, but failed to find any important difference between them. He reached the conclusion that they were efficacious as disinfectant agents.

Reinicke (1895) found the resisting power of soaps to the potassium soaps in 5 per cent. solution very considerable.

Beyer in his experiments of 1896 studied the effect of soft soap in 3 per cent. solution in disinfecting soiled linen. His results were to the effect that they could be disinfected by prolonged immersion. Reithoffer, in the same year, worked up the effect of potassium soap in the cholera, typhoid bacilli, and the staphylococci, and stated his belief in its real antiseptic power.

Serafini, in 1898, recognized soap as a very important disinfecting agent, and called attention to the fact that the discordant conclusions of other experimenters were due to the diversity of conditions under which their experiments were conducted.

Foerster (1900) came to the opinion that soft soap was inefficient for the disinfection of linen. Other soaps were more active.

In 1902 Conradi emphasized the important part played by the aromatic principles of scented soaps. He used very weak solutions and failed to get any particular effect.

Marx, in the same year, studied the aromatic principles of potassium soap, but his conclusions are not stated.

Nocht, Henle, and Heider experimented with the so-called antiseptic soaps, and Heller, in 1903, experimented with carbolated soap in various proportions.

*Read at the annual meeting of the New Jersey Sanitary Association, held at Lakewood, December 3, 1915.

Conradi, in 1904, experimented with more than a hundred varieties of commercial soap, using exclusively the anthrax bacillus. His conclusions were that there was no effect upon this germ unless mixed with aromatic substances.

Such is the history of the experimental work done up to recent times. It can be seen that the views do not thoroughly harmonize, and it is a question whether, according to them, soap is at all effective in the control of bacterial life. But, when we read the reports with the knowledge of much of the work being done in the laboratories, perhaps some of the results may be explained.

All of the experimenters, or nearly all, used weak solutions. The soaps employed by many were of the poor commercial type. Some used the potassium soap, others the sodium. The amount of water the soap contained is not mentioned, so that the true percentage of the solution is open to question. The quality of the water employed varied with the locality. Some experimenters studied for the antiseptic action, others for the bactericidal effect. Many of the investigations were upon a rare type of organisms, the anthrax bacillus, very little effort being made to study the effect upon the more common disease-producing forms, such as the staphylococcus, streptococcus, and colon bacillus. In none of the experiments was the temperature of the water made an important factor.

Then again (and the main point of all), in some cases the microbes were put on threads and hung in the preparation, while in other instances they were entangled in albuminous masses.

One very important fact is demonstrated by all the work done by the bacteriologists in the study of soap solution, as well as in the study of other bactericides, and that is, that the germs do not all die at once. Whether it be soap, carbolic, or sublimate, the germs begin to die soon after the application is made, but the last germ is not killed for a considerable time later. It is inaccurate to say that an antiseptic of a certain strength in solution at a certain temperature kills germs at a certain time, because some germs possess a greater resisting power than others and will endure against the antiseptic action for a more considerable period.

Soap as used is not in solution, *per se*, but there is a separation into its ions, and it is taken and applied, according to most writers, in about a 10 per cent. strength, yet few of the experimenters give us the result of a 10 per cent solution.

All the experimenters did not have the same object in view. Some looked into the effect of the preparation on linen, while others looked upon the effect on the skin. But in one thing they are in accord, and that is, an antiseptic added to a soap is diminished in efficiency thereby, and diminishes the efficiency of the soap itself.

Wright says "everything hinges upon whether the laboratory experiments which we trust accurately reproduce the conditions they are supposed to effect. Now, the early experiments on antiseptics (and it is always upon the antiquated experiments the mind of the doctor of the day rests) did not even aim at reproducing practical conditions. The antiseptics came into the application not as they are used commercially, but upon microbes simply suspended in water. Can it pass as an axiom that if *in vitro* all the microbes were destroyed, then also all the microbes *in vivo* would be destroyed?"

Later day researches are, perhaps, more valuable and possess greater reliability. The object of this

paper is to present them, also, so that a new viewpoint may be taken and a more accurate estimation of the value of soap as a bactericide obtained.

Symes,¹ 1909, studied to determine two things: whether plain toilet soap might not be a medium in which germs could flourish, and whether it might not be of advantage to use a disinfectant soap. He used the *Staphylococcus pyogenes aureus*, the commonest and most resistant of the pus organisms, and experimented with six types of soap. He answered the first question, "can germs live and multiply on soaps," with the statement that all soaps possess antiseptic properties in some degree and that the germs rubbed into soap or dropped on its surface are not capable of multiplication. Of all the soaps tested the most antiseptic property was contained in the biniodide of mercury soap.

His second series of experiments was as to the disinfecting value of soaps. He made many observations, running over a number of months, and came to the following conclusion: 1 per cent. solution of germicidal soap with biniodide of mercury kills the *Staphylococcus aureus* in 1 minute, while the same strength of other soaps, with or without the antiseptic, fails to do so in from 10 minutes to 3 hours. He noted the fact that all organisms are not affected alike by soap solutions. The cholera vibrio, typhoid bacillus, colon bacillus, and streptococcus are killed much more quickly or by much more diluted solutions than the staphylococcus.

He concludes from his experiments that for practical purposes most so-called disinfectant soaps have no value, but in a combination of biniodide of mercury with soap we have a useful means of disinfecting hands, instruments, and surfaces, although he never succeeded in completely sterilizing the hands.

Championnière,² writing in 1910, says that "those who are most strongly opposed to antiseptics are at the present time studying it under various forms, such as the use of tincture of iodine, and soaps." In practice there are numberless sterilizations which can be carried out in a proper manner by using soap in concentrated solution. He feels it would be interesting for some research worker of the day to study soap as iodine, carbolic, and the sublimate have been studied. "The use of antiseptics is current. The object of new methods should be to choose those which are powerful, useful, and inoffensive, according to the requirement of the cases to which they are to be employed. The first place in common antiseptics must certainly be given to soaps. It must not be forgotten that in these times of sepsis the requirements of sterilization are everywhere encountered, even in places where a complete apparatus is not at hand, and it is not wise to neglect anything which may play a really active part and to put every one in a position to effect an indispensable antiseptics with means common but sure. Numerous experiments have emphasized the great antiseptic value of soap, so it is of highest importance to determine its exact action. It is necessary to ascertain whether very complicated methods of certain sterilizations are not inefficient and inferior to the use of soap, which belong to the immense class of unconscious antiseptics, practised in pursuance of a scientific doctrine or because experiment and tradition have established a necessity.

"No practical result will be accomplished by merely studying the absolutely antiseptic value of the substance by means of a simple experiment *in vitro*. The circumstances in which the substance is

employed, the association into which it is forcibly introduced, and complex actions may destroy its properties, and all these facts must be thoroughly established. Soap dissolves the fat bodies and dismembers the albumenoid matter. Whereas in vitro soap appeared infinitely less antiseptic than the metallic salts, it maintains a powerful action at a time when other antiseptics have absolutely no action whatever."

Rodet's article⁶ on "The Antiseptic Value of Common Soap," published in 1905, is the most exhaustive treatise we have. After a careful laboratory research, made under conditions which simulate those to which soap is ordinarily and practically applied, he came to the conclusion that soap solutions are manifestly endowed with a destructive power with regard to staphylococci: 1 per cent. solution is very slow in effect and little active, but its bactericidal power is not altogether negligible; 5 per cent. solution is much more active and possessed of considerable power. In the first minute a number of elements are killed and very soon few are left, but these latter survive for a long time, and take hours to be destroyed, as if, amongst the elements of a staphylococcus culture, there were a certain number, which, in regard to soap (and would it not be the same in regard to other antiseptics?), behaved as resisting elements and played the part of spores or durable forms.

The typhoid bacillus is much more sensitive than the staphylococcus. A 5 per cent. solution is very active and kills the bacilli in a short time, the larger number being killed in less than a minute.

All bacilli immersed in soap solution are not killed at the same time. They are touched successively, probably due to an inequality in the resisting power of the various germs in the same culture. Plain soap possesses a real antiseptic power with regard to the staphylococcus and typhoid bacillus, the latter being more sensitive to it.

Our profession has been under the influence of the laboratories. Since the time they became effective in various techniques their impress has been very great, as they seem to possess a shortcut to the explanation of many things and to the perfection of diagnosis. Perhaps good old-time common sense has been neglected and the laboratories resorted to in its place. Through them we have attempted to investigate and to test out the action of disinfectants, but the biggest and best laboratory of all is clinical experience, particularly that of the unconscious type. Can we not see that the professions, sanitary and medical, are gradually becoming suspicious of the value of antiseptics and that there is a trend toward what we used to call hygiene because of our lack of knowledge, but now know to be nature's sanitary antiseptics: soap, water, and sunshine?

Almost all clinics devote considerable time to scrubbing with a potassium soap, the lather put on estimated to be of 10 per cent. strength. Unna, after a preliminary wash, pastes potassium soap over his hands and arms, rubbing it until fairly dry, then puts on gloves and proceeds. Even the educated surgeon, after washing, fails to keep his hands and arms in the antiseptic mixture until the last germ has been killed, but splashes a little and goes to his gloving.

The leading boards of health in our more advanced cities have stopped fumigation and spraying with antiseptics of the laboratory and are depending upon soaps.

A potassium soap made of pure materials, not hurriedly used, we now know not only cleanses, but, by its sustained action materially cuts down germ life.

MEDICAL INSPECTION AND ANTHROPOMETRIC STUDY IN THE UNIVERSITY OF PORTO RICO.

By LUIS A. SALIVA, M.D., G.P.H.

RIO PIEDRAS, P. R.

MEDICAL INSPECTOR, DIRECTOR COLLEGE OF PHARMACY,
UNIVERSITY OF PORTO RICO.

THE Board of Trustees of the University of Porto Rico, in its meeting of July 19, 1915, adopted a resolution that Medical Inspection and Anthropometric Study of the students of the University should be undertaken. This is the first time that work of this character has ever been done in Porto Rico.

I was appointed by the Dean of the University as Medical Inspector, and the inspection and anthropometric study were begun in September, 1915, at the opening of the present school year. The examination being now completed, I have thought it might be of interest to the people of Porto Rico and to people interested in anthropometric work outside of the island, to publish the results obtained, since work along this line will be carried out in a very short time by the different public and private schools of the island. Complete medical inspection of schools has been carried on in some cities and States in the United States for the last twenty years. The results attained have more than justified the existence of medical inspection of school children, this being the surest way of safeguarding the life of the young people going to public schools, by preventing the spread of contagious diseases and by correcting malformations. As Dr. S. W. Newmayer of Philadelphia says: "We realize that the progress of our civilization, the welfare of the individual and the general good of society are contingent upon the efficiency of the education imparted to the children in the public schools. To take advantage of such opportunities, children must be physically and mentally equipped." Upon the inspection of the public schools of Porto Rico depends the future physical welfare of the people of Porto Rico.

These few items, though not pretending to contain the last word on the subject, might also be of interest in establishing a comparison between what the people of our island are physically, and what they should be; and between what the development of our young men and women is, as compared with the development of young people of the United States and other nations of the world.

The data presented are the result of the examination of 514 students of whom 220 were males, and 294 females.

Average age of girls, 18.30 years.

The average age of the males examined was 19.07 years; their height was 65 inches, and their weight 113.52 pounds. The young men of the same age in the United States average 67.88 inches and weigh 137 pounds. It will thus be noticed that our Porto Rican boys are about two inches shorter and weigh 23.48 pounds less.

The average age of the girls examined was 18.03 years, their height being 61.41 inches, and their weight 106.94 pounds. Comparing, again, these figures with those of American girls of the same age, *i.e.* 63 inches and 120 pounds, we shall see that our Porto Rican girls are 1.59 inches shorter and weigh 13 pounds less than the girls in the States.

Following was the order of examination. Age; height; weight; neck measurement; measurement across the shoulders; chest, natural, anteroposterior, transverse, muscular, after full inspiration, after full expiration; waist; hips; right arm down, right arm up; left forearm; left thigh; left calf; lung pressure; sight; hearing; condition of the teeth; adenoids; heart, lungs. Would drill or ordinary gym. work be injurious? Special exercises recommended.

The above items were printed in blank form, and numbers were used instead of the students' names in keeping the records.

In the examination of the chest, the average expansion was found to be 2 inches. The average pressure, 2 pounds. In the examination of the eyes, simple and granular conjunctivitis, strabismus, astigmatism, myopia and hyperopia were looked for. Out of the 514 students, 285 were found to be suffering from their eyes, 180 of these had myopia and astigmatism; about 85 had hyperopia and simple conjunctivitis, there being four cases of granular conjunctivitis.

The watch was employed for testing the hearing; 60 out of 514, *i.e.* 8.5 per cent. were deaf in one or both ears. One student had suppurative otitis media.

Out of the number examined 316 had decayed teeth, there being only 198 whose teeth were in good condition.

In the examination of nose and throat, enlarged tonsils, adenoids, defects in breathing and speech were looked for. Of these, there were 14 cases of adenoids; 2 had defects in their speech; 2 had defects in breathing. One case of acute tonsillitis was noted.

In the examination of the heart, its position, valve murmurs, bradycardia, and tachycardia were looked for. Fifty students were found to have hemic murmurs, probably due to their anemic condition. Further examinations are being made to ascertain the cause. There were 2 cases of tachycardia.

Mentality tests were not carried out in this first examination, but will be given in our next examination at the end of the school year.

A study of the accompanying charts, one for the boys, the other one for the girls, will illustrate graphically the work accomplished.

Sterilization of Water by Ultra-Violet Rays.—Parkinson reports favorably on this method of sterilization of water, and the treatment of turbid water has met with remarkable success. For a constant result the quartz mercury lamp, employed in this work, must be burning under a constant voltage and be in good condition. The action of the rays is apparently entirely physical. —*Thirty-third Annual Report, Provincial Board of Health of Ontario.*

PLASTERERS' CORNS AND BUNIONS.

BY GUSTAV F. BOEHME, JR., B.S., M.D.,

NEW YORK.

NEUROLOGIST TO THE WEST SIDE GERMAN DISPENSARY AND HOSPITAL; ASSISTANT PHYSICIAN, NEUROLOGICAL INSTITUTE.

In the last few years occupational ills of all varieties have been investigated, but as a rule only from the angle of the patient's constitutional condition. The workers in metals, in chemical factories, in the manufacture of matches, those who are injured generally by noxious fumes and gases have all been investigated and prophylactic and curative means for their ills have been devised. There are, however, a number of minor complaints which are due directly to occupation, that have been ignored completely, and it is the province of this paper to call attention to one such condition, with a suggestion for the means of its prevention.

Some time ago there came into my office a patient who worked as a plasterer and I noted, in chatting with him, the peculiar deformity of his hands. On asking him how they had gotten into this condition he laughed and said, "All plasterers have

FIG. 1.—Position of "Bunions" and "Corns." a, bunions; b, corns.

them; we call the big ones "bunions" and the small ones "corns."

Clinically the condition presents itself as follows: Over the external aspect of the metacarpophalangeal joint of the thumb there is noted a large bursa, varying in size from a quarter to a little below a fifty cent piece. This protrudes exactly as a large bunion does in a corresponding position on the feet. A similar bursa, usually smaller in size, is present over the metacarpophalangeal joint of the index finger.

Over the first interphalangeal joint of the index finger, and the corresponding joint of the thumb, two hard callous areas are present, exactly the same in character as the corns on the feet. These among plasterers are in fact known by that name.

The etiology of the condition is interesting. They occur more commonly on the left hand (as most plasterers are right handed) and are produced in the following manner: The plasterer holds in his left hand a flat board about sixteen inches square to which, at its center, is attached a round stick six to eight inches long. This central handle is held in the hand, the board resting flat upon the closed fist so that it gains its support from the metacarpophalangeal joints and the flat

surfaces of the thumb and index finger. Upon the board is placed a large pile of plaster weighing from six to eight pounds. With his trowel the plasterer now removes the plaster from the side nearest to him of this instrument known to the workers as a "hawk," and gradually, as he uses the material, rotates it in his hand, bringing new plaster near him. Acting therefore for six to eight hours daily upon the hand, there is a pressure of six to eight pounds weight (accentuated by gravity, in foot-pounds of work, dependent upon the elevation of the job), in conjunction with the constant friction produced by the rotation of the hawk. The end result is at first a subacute inflammatory process over the joints described, followed by the gradual development of the two large bursa, "bunions" as they are called in the business, with callouses, known as "corns," on the other points of pressure. The deformity in advanced cases is marked, and is not at all a pleasant condition to present to public view.

The therapy in this condition I believe should be directed toward prophylaxis, and I believe that I have devised a "hawk" which will do away entirely with the condition. It is simple in con-

By means of this simple variation of an old-time tool the writer believes much discomfort and pain can be prevented, besides the avoidance of a permanent and unpleasant deformity of the hands.

As to the treatment, the method varies with the degree of the process present. In the early cases stopping the work temporarily, with local soothing applications will restore the hand to normal. The subsequent use of the above described hawk should prevent its recurrence.

In cases of long standing actual "bunions," *i.e.* inflamed bursæ are found, and these must be treated like these bursæ elsewhere. The callouses can be removed in the usual manner, by means of caustics, or any of the salicylic paints or salves.

There are numerous minor ailments of this kind occasioned by occupational instruments and manoeuvres. This is but one of them; further study will present similar conditions, and their treatment along prophylactic lines is not to be neglected—at least no more so than that of the constitutional ills.

220 AUDUBON AVENUE

Medicolegal Notes.

Privileged Communications—Waiver by Failure to Object.—In an action for personal injuries the most important and difficult question was whether, under the Minnesota privileged communications act, a patient, if he fails to object to a question which necessarily calls for testimony which is privileged after a fair opportunity is given him to make an objection, waives his right to object that the physician cannot testify. The testimony in question was as to a physical ailment existing prior to the accident. "There is no question," said the Court, "but that this testimony is inadmissible, unless the plaintiff made it inadmissible by waiver. There was no express waiver. If there was a waiver, it must be because of a failure to object at a proper time. There is much to be said in support of the policy of limiting the statutory restriction or of modifying the statute. Dean Wigmore makes a forceful argument against the rule of privileges. 2 Wigmore Ev. secs. 2388-2389. It is followed in an incisive opinion in *Epstein v. Pa. R. Co.*, 250 Mo. 1, 156 S. W. 690, 48 L. R. A. (U. S.) 894, Ann. Cas. 1915A, 423, and in other cases. The complaint usually is that a plaintiff, seeking damages for an injury, is unfair in repressing and keeping from the jury the testimony of a physician who treated him and has knowledge of his condition at the time, when the physician's testimony, if truthfully given, should be helpful to the jury in reaching a right determination of the extent of the injury for which compensation is sought. There is much force in this suggestion; yet there are those who say that the complaint made is unjust, in that it prescribes an arbitrary test of fairness for the plaintiff, and leaves the physician who attended him at the time of his injury, and whom he did not employ, and who may be a partisan of the defendant, restrained by no rule of fairness, except such as his conscience gives. It is likely that the whole question is not of such far-reaching importance as some give it, for juries see the practical situation and measure testimony accordingly. This court voiced its understanding and appreciation of the standpoint of *Wean Wigmore* in *Hilary v. Ry. Co.*, 104 Minn. 432, 116 N. W. 933, and notably in the late case of *Marfia v. Great N. R. Co.*, 124 Minn. 466, 145 N. W. 385. We are not concerned with the question of the policy of restricting a physician in his testimony. The Legislature has fixed the policy and stated it in the language of the statute quoted. The question of waiver, however, is a question for the court; * * * and it is the view of the majority that when a question is asked a physician, necessarily calling for testimony which is privileged under the statute quoted, and a fair opportunity is given the plaintiff to make an objection, he must make it then or lose his right to object afterwards during the trial. * * * A minority of the court do not agree with the conclusions stated."—*Burke v. Chicago & N. W. Ry. Co.* Minnesota Supreme Court, 154 N. W. 960.

FIG. 2.—Model of improved hawk for plasterers' use.

struction and should not be of great added expense to the plasterer, especially when he considers that a real deformity is prevented thereby.

In Fig. 2, A is a hawk of oval shape slightly larger than the hand. In its center (a) is a hole leading into a hollow handle (b). B is a similar hawk, the top of which is of the usual size employed in work. The handle (c) slides into the hollow handle (b) of hawk A and the whole hawk B can be rotated on its axis within this hollow shaft. The edges of the superimposed hawk B are notched to allow the workman to rotate it by a touch from his trowel. The lower surface of the hawk A should be padded with hair and leather to prevent undue pressure.

In practice the hawk A is grasped in the left hand, the hawk B is slid into hawk A (as Fig. 2, C), plaster to the usual amount is superimposed. As plaster is needed the upper hawk can be rotated upon the lower, thus entirely avoiding the constant friction on the hand of the worker. The padding also helps to prevent pressure on the bony prominences supporting the instrument.

THE SOLDIER'S HEART.

ACCOUNTS of wounds in war, their nature and treatment have filled many pages of the medical journals since the outbreak of the war in Europe, and already a voluminous literature has accumulated on the subject. From the medical standpoint not so much has been written for the very good reason that, on the whole, disease has been conspicuous by its absence among the soldiers at the front. There has been no great epidemic, with the exception of that of typhus in Serbia, and the health of the soldiers, at any rate, of those at the French front, has been quite remarkably good. Nervous affections brought about by strain and shock have been fairly frequent. A somewhat extraordinary feature of the campaign in France is that a large proportion of tuberculous subjects serving in the French army are said to have been greatly benefited by the exposure and the hard life which they have been compelled to lead.

With regard to heart affections, it is manifest that the trying life of the soldier, the stress of life in the trenches, the shocks which he has encountered, and the varied vicissitudes to which he has been exposed have placed an undue strain upon the heart. Naturally when the heart is impaired, such a life as the soldier must lead will find out the weak spots and render its possessor unfit for military duty. But, as Sir James Mackenzie pointed out in a paper read in opening a discussion in the Section of Therapeutics of the Royal Society of Medicine (*British Medical Journal*, January 22), such cases form but a small percentage of those that are actually invalidated on account of their hearts. He further pointed out that it has long been recognized, particularly since the instructive account published by Weir Mitchell and other physicians during and after the American Civil War, that there is a form of heart trouble to which soldiers are particularly liable and which has gone under the name of the "soldier's heart" or the "irritable heart of soldiers." Mackenzie during the past year has had opportunities for studying heart disorders of soldiers, and in association with Dr. Wilson has examined about 400 cases. They found that at least 90 per cent. of the cases that had been certified and treated as heart affections were not primarily heart cases, and that the principles of treatment applicable to these cases were widely different from those called for in heart failure.

After describing the phenomenal characteristics of the soldier's heart, Mackenzie concludes that the condition is one of general exhaustion and the circulatory symptoms are but parts of a general manifestation. In order that this point may be appreciated more clearly, he differentiates between an infected heart and chronic disease of the heart. In some cases of infected heart there may be doubt as to whether the condition may not be due to an infection of the heart itself. It may not be possible to settle the question while there is a rise of temperature, so judgment will have to be deferred until the fever subsides. If the temperature remains raised for a period of weeks, and no source of infection can be found, then the suspicion that there is an affection of the heart becomes strengthened. With the permanent fall of temperature, the heart can usually be assumed to have escaped infection and the abnormal manifestations—rapid beat, systolic murmur, and increase in size—may be taken as a reaction of the heart to a toxin, or to the factors that produce a general exhaustion. In chronic heart disease the first sign of a failing heart affected by some old standing lesion is invariably a subjective one, due to a distressful sensation arising when some effort is made which the individual used to perform with no discomfort. By far the most common sensation occasioned in this way is breathlessness; the next most frequent pain. Both these may be associated with palpitation. These are sensations which everyone recognizes as indications of inefficiency of the heart. In the poisoned heart these are usually not the first signs, though they also appear, the first sign being the sense of exhaustion. Such heart abnormalities are, according to Mackenzie, but a feature in a general condition. In short, the view taken by the great British authority is that the cause of the disorder is some bacterial or toxic influence, although he acknowledges that the grounds for this belief are solely clinical.

The treatment recommended for the condition should be one which tends to increase the health of the body as a whole in such a way as to increase the natural resistance to infection, to eliminate toxic influences and to brace up the whole man bodily and mentally. In Mackenzie's opinion the best way to achieve this result is by fresh air and judicious exercise in the fresh air. Attention is drawn to the fact that there is a deeply rooted notion that if there is anything wrong with the heart the patient must be restricted in the amount of effort, and indeed the common belief among physicians is that the best mode of treatment is rest in bed or, as Mackenzie puts it, going about gingerly. He entirely disapproves of this, however, and, as said before, advocates judicious exercise in the open air.

FREE OMENTAL GRAFTS IN ABDOMINAL SURGERY.

SOMETHING over a year and a half ago (August 8, 1914) we called attention to the value and gradually increasing field of application of free fat and fascia transplantation, and since then Lexer and others have contributed exhaustive articles on the trans-

plantation of tissues and organs. The results in many instances have been little short of marvellous; and from the numerous reports of such successes in the literature it is evident that surgeons have been generally quick to grasp the possibilities of tissue transplantation.

In view of this fact it seems strange that more use has not been made of the omentum in intraabdominal surgery. Here is a fatty structure ready and waiting to be used in certain classes of cases and still, as Freeman (*Annals of Surgery*, January, 1916) says, there seems to be a general failure to recognize the important surgical uses to which it may be put, and especially is this true of free omental grafts. Freeman calls attention to the fact that the omentum seems almost intelligent in seeking out and attaching itself to raw and inflamed surfaces, wrapping itself around them in such a way as to afford a maximum of protection; and that when the inflammation has subsided or the need for protection has ceased these adhesions tend to disappear. He then discusses a number of conditions under which omental grafting may be profitably employed, such as the replacement of lost portions of the peritoneum; the prevention of adhesions; the strengthening of suture lines in operations upon the stomach and intestines; pyloric and intestinal occlusion; and the checking of hemorrhage, particularly parenchymatous oozing from the liver or spleen.

The technique of omental grafting is simple, but Freeman calls attention to the following precautions which are to be observed: (1) In tying off the graft a sufficient number of ligatures should be used so as not to pucker the pedicle into too much of a bunch. (2) The excision should be made as far from the base and as near the free border of the omentum as possible and an effort made to avoid the larger vessels, for reasons mentioned further on. (3) No more tissue should be sacrificed than is actually required. (4) The grafts should always be held in place by a number of stitches of fine catgut, in order to guard against their shifting. Silk or linen sutures are unnecessary, owing to the remarkable rapidity with which adhesion of the grafts occurs. (5) The transplant should entirely cover the raw area and project over the sound tissues on every side.

There are, however, certain objections to omental grafts which Freeman thinks should prevent us from employing them too hastily. These are: (1) The production of multiple foci of hepatic necrosis; (2) the causation of gastric and duodenal hemorrhage; (3) the loss of a useful organ which might be required for other purposes, and (4) the production of a raw omental stump capable of forming objectionable or even dangerous adhesions. He does not consider that there is much force to any of these objections, for the probability of their occurrence is remote to say the least. Gastric hemorrhage and hepatic necrosis are of the greatest interest and are probably both due to emboli arising from thrombosis of the vessels following ligation of the omental tissues. However, he quotes Friedrich for the statement that such happenings "belong among the rarest clinical phenomena," and when they do appear the prognosis is usually good.

There can be no doubt that omental grafting is a resource of great value in selected cases. Certain general indications may be stated, but the use of the graft in the individual case must always depend upon the possibly complex conditions that may be present and the ultimate decision will depend also upon the surgical judgment, skill, and experience of the operator. In certain adhesion cases, after cholecystectomy when there is parenchymatous oozing or difficulty in covering in the raw surface, after the separation of ileal kinks and bands, to reinforce the suture line after the excision of a gastric or duodenal ulcer—these are a few of the conditions in which omental grafts may be advisable; and doubtless more use will be made of this resource as its value is better appreciated.

POST GRADUATE INSTRUCTION IN MEDICINE.

WHEN a man has received the degree in medicine, as a rule, he is not fully fitted to practise; he must gain experience in hospital or dispensary work ere he is adequately qualified to perform the duties of a general practitioner. Moreover, after he has been practising for some time he is apt to get rusty or rather he is not well acquainted with the improvements in medicine and surgery that are constantly taking place. In order to be in every way competent to do his duty to his patient he must keep in touch with all the advances of medical and surgical science. For the majority of practitioners the best means of successfully achieving this object is attendance at some post-graduate school of medicine.

In the *Interstate Medical Journal*, March, 1916, is a paper by Dr. Frank Spooner Churchill of Chicago dealing with the subject. He sketches the ideal hospital for post-graduate teaching and especially emphasizes the value of post-graduate teaching in pediatrics. The principles discussed in Churchill's paper are summarized as follows: (1) Post-graduate study and instruction in medicine are desirable both from a private and public point of view; from the private points of view they enable the individual practising physician to keep himself informed as to progress in medical science, thereby making him a better workman and increasing his prestige and standing in his own community; and secondly, from the public point of view, in that it ensures to the public well trained and well informed physicians, an inestimable benefit to any community. (2) The opportunity for physicians to keep themselves so informed is best found at a teaching hospital connected with the medical department of a university, such a hospital being located preferably in a large medical center, in order to secure an abundance of clinical material. (3) To make the clinical material available for teaching, the hospital must be well organized and well equipped, the material well classified. (4) While opportunity should be provided for physicians to develop themselves into specialists and research workers, the greatest importance attaches to the needs and demands of the great body of general practitioners. Therefore (5) instruction should be made as practical as possible, patients being studied at the bedside and in the

laboratory; and (6) The teaching should be as individual as possible; hence classes or groups should be small in number. (7) Undergraduates and post-graduates in medicine should not be taught in classes together, so different are the demands and needs of the two groups.

PLASTIC SURGERY OF THE FACE.

THE present war, especially as it is carried on in France and Belgium, has been distinguished by certain outstanding features. The first of these features is applicable to the war generally, namely, the use of such high explosive shells as have never been employed in warfare previously; the second is the trench fighting, chiefly waged in France and Flanders, and the third is the use of gas. A striking feature of the wounds resulting from this mode of warfare is that so many in the prime of health and strength are almost hopelessly mutilated. Some are crippled and disfigured nearly beyond recognition, and in France, at any rate, the greater proportion perhaps of these are wounded in the head and face. This is due to the fact that in trench warfare the upper part of the body is the most exposed, and to the employment of high explosive shells and shrapnel. In no war have there been so few wounded by rifle bullets. It goes without saying that a very large number of the head and face wounds have been of a terrible nature. At a meeting of the Eastern Medical Society of the City of New York held on February 11, 1916, Dr. W. Seaman Bainbridge read a paper on some effects of war as seen by himself, the paper being illustrated on the screen. Among the many aspects of the war depicted were several pictures of face wounds which were successfully treated by Dr. Blake, late of New York, and by Dr. Hayes, an American dentist. As an illustration of what skilful plastic surgery can accomplish, these pictures were wonderful. However, plastic surgery has reached a very advanced stage of development. In the *Journal of the Royal Army Medical Corps* for December, 1915, is a paper by four British dentists, Messrs. Hopson, Payne, Pearce, and Mummery, dealing with plastic surgery of the face and drawn from their experience of jaw injuries which had occurred among British soldiers fighting in France. They tabulate their principles of treatment as follows: (1) Reduction of the displacement and maintenance of the remaining fragments during healing of the parts; (2) stretching of the cicatricial tissue and remoulding of the facial contours; (3) fitting of a permanent prosthetic appliance to replace lost parts, restore function, and preserve the facial outlines.

SIMPLE PRURITUS.

PERHAPS no physician ever lived who has brought to bear so much of effort to determine the exact pathology and rational treatment of disease as the dermatologist Unna. The reason for this lies in the comparative absence of drawbacks connected with a study of disease of superficial tissues. Unna also offers the almost unique combination of a laboratory and clinical practitioner and a high type of each. No one is more exhaustive in the study of histology and histochemistry, nor more original and resourceful as a therapist. In the *Berliner klinische Wochenschrift* for November 8 Unna briefly sums up the subject of simple pruritus.

presumably as it affects or might affect the soldier. The affection is either universal or reappears in successive localities. Any toxic substance which is a reducing agent and can damage the endothelial nerves of the blood capillaries may set up a pruritus which will subside only with the withdrawal of the cause. This affection is not very prevalent among the troops and is usually due to one of a few causes, as tobacco, icterus, and involutional changes in the skin, the latter being a predisposition which is activated by unknown circulatory toxins. In civil life diabetes and albuminuria are frequent causes of simple pruritus. The treatment must necessarily be eliminative. Locally oxygen baths and strong oxidizing applications neutralize the poison because these are themselves reducing agents.

THE THORAX PARALYTICUS.

THIS anomaly is sufficiently described in various textbooks, but is by no means an entity. There are differences of opinion as to whether it is congenital or acquired and speculation as to its relationship with the habitus asthenicus. At a recent session of the Berlin Medical Society (*Muenchener medizinische Wochenschrift*, December 7) Virchow showed a dissection of such a thorax. It had a narrow aperture and a long manubrium, which explained the anterior width of the intercostal spaces which were correspondingly narrow behind. A firm connection of the first rib with the sternum is necessary for the performance of its function and has no relationship to a phthisical apex. Respiratory gymnastics, especially singing, can favorably alter the shape of the thorax. In discussion von Hanse-mann stated that ossification of the first cartilage was not a phenomenon of vital significance; the form of the first rib had much to do with the aperture of the chest. Wolff-Eisner spoke of radiographs of the tuberculous thorax. Only now and then was the first cartilage ossified. This phenomenon could be ascribed in part to ossifying perichondritis. Kausch alone upheld Freund's doctrine that ossification of the first cartilage was a determining causal factor of pulmonary tuberculosis.

THE STERILIZATION OF SPUTUM SPECIMENS.

ONE of the ever-present dangers to which the laboratory worker is exposed is that of infection from the specimens which are submitted to him for examination. This is an especially great danger in the case of sputum, since the outside of the container is more apt to be contaminated. A method which eliminates this danger has been devised by Griswold (*Jour. Lab. and Clin. Med.*, 1915, i, 189). He autoclaves the specimen in the sputum bottle for twenty minutes at twenty pounds pressure and 120°. This sterilizes bottle and contents and causes a separation of the specimen into two layers, an upper watery one and a lower, more solid, layer having about the consistence of butter. This consists largely of coagulated albumin and contains most of the bacteria of the sputum. This material gives a thin even smear which is readily stained and examined. Control tests showed that the tubercle bacilli stained as well after autoclaving as before and cultures and animal inoculations showed that the material was sterile. The cleanliness and safety of this method should commend it to all laboratories as being worthy of adoption when culture tests are not to be made.

News of the Week.

Military Training.—The College of Physicians and Surgeons, Columbia University, announces a course of lectures on military administration, medicine, and surgery, to be given at the college on Tuesday afternoons at 5, beginning on March 28. The lectures will be open to the general medical public as well as to the students of the college. The course is as follows: March 28, "Organization, Equipment, and Training of Armies," by Lieut.-Col. W. S. Terriberry, Medical Corps, N. G. N. Y.; April 4, "Organization in the Medical Department, and Its Service in Campaign," by Major Joseph H. Ford, Medical Corps, U. S. A.; April 11, "Wounds in War, Their Complications and Treatment," by Major Ford; April 18, "The Personal Hygiene of the Soldier," by Major S. H. Wadhams, Medical Corps, U. S. A.; April 25, "Camp Sanitation," by Captain P. W. Huntington, Medical Corps, U. S. A.; May 2, "Preventable Diseases in War," by Captain Huntington.

New Dental School.—As previously announced, the Faculty of the College of Physicians and Surgeons, Columbia University, New York, realizing the importance of the relation of infections of the teeth and mouth to systemic disease, has unanimously voted in favor of the establishment of a dental department in connection with the medical school. This will be the first university dental school in New York City and the second in the State. The admission requirements for the dental school will be the same as for the medical school, and the first two years of the four-year course will be the same as the first two years in medicine, thus insuring for the dental student a thorough knowledge of the fundamental sciences necessary to the practice of medicine. After the second year the dental student will give all his time to the study of dental subjects: operative dentistry, prosthetic dentistry, oral surgery and oral pathology, orthodontia, etc., and the more technical part of the work required for the well-trained dental surgeon. The school will be the first in New York State to give a four-year course in dentistry.

A Pay Clinic.—Mt. Sinai Hospital, New York, announces the establishment of a clinic for paying patients to be conducted by the hospital, in the belief that there exists in this city a need for pay clinics where ambulant patients in moderate circumstances may consult reliable specialists without being compelled to pay office fees beyond their means. The clinic will be held on week-days from 7.30 to 9 P. M., and the patients will be restricted to those whose incomes are under \$1,200 a year. Opportunities for consultations between outside physicians and the clinic doctors will also be provided.

Rockefeller Foundation.—Among a number of appropriations recently made by the Rockefeller Foundation, New York, are the following: To the Rockefeller Institute for Medical Research for additional endowment needed in connection with the Department of Animal Pathology at Princeton, N. J., for the study of animal diseases, \$1,000,000. To the Institute, also, for the cost of medical research and such medical supplies and services as the Institute may appropriately furnish at the seat of war in Europe, \$25,000. To the China Medical Board for the purchase of additional property adjoining the Union Medical College, Peking, thus increasing the facilities for the promotion of medical teaching in

China, \$125,000. The major part of the second appropriation mentioned will be used for the support of the hospital and research work conducted by Dr. Alexis Carrel at the hospital in Compiegne.

Fight Over Mohansic Site.—At a recent conference between Governor Whitman and the Republican leaders, the decision was reached to put through the Legislature a measure providing for the abandonment of the Mohansic State Hospital and the Yorktown Heights Training School for Boys on the Croton watershed. An effort is being made, however, to strangle the bill in committee.

The Harrison Law in Texas.—Forty physicians in the State of Texas have been convicted of violating the Harrison law governing the use of narcotics, and the State Medical Board, at a recent meeting, decided to ask for the revocation of their licenses.

Medical Legislation.—There has recently been introduced into the United States Senate a bill providing for the establishment in the Department of Justice, a bureau for the study of the criminal, pauper, and defective classes, to include laboratory investigations and the collection of sociological and pathological data. The bill provides for the appointment of a director, a psychologist, and clerical helpers, the total cost of the bureau to be about \$15,000 per annum.

Deaths of Foreign Medical Men.—Dr. Gilbert Ballet, professor of mental diseases in the Faculty of Medicine, University of Paris, died on March 17.

Dr. Léon Labbé, the well known surgeon of Paris, member of the Institute and of the Academy of Medicine, died on Tuesday of this week. He was born in Mericault in 1832.

Dr. Pietro Grocco, director of the medical clinic at the University of Florence and a senator in the Italian Parliament, died of pulmonary tuberculosis the latter part of February.

Reorganization at Randall's Island.—Dr. William B. Cornell of Baltimore, executive secretary of the Mental Hygiene Society of Maryland, has been appointed by Commissioner Kingsbury as medical director of the New York City Child's Hospital and Schools at Randall's Island, and the institution is to be completely rehabilitated and reconstructed. The city has made an initial appropriation of \$600,000 to start the work of rebuilding and reorganization in the right way, and it is understood that \$1,000,000 in addition will be forthcoming to complete the work. Dr. Cornell is a graduate of the Johns Hopkins Medical School, in 1903, and has had considerable experience in the care of the insane and of defective children. He assumed charge of the institution early in March, this being the first time in the history of the place that a medical man has been at its head.

Dr. Carlos Husk, chief surgeon of the American Smelting and Refining Company, who had been working with the doctors sent by Mount Sinai Hospital, New York, in studying typhus in Mexico, died at Laredo, Texas, from typhus fever on March 20. Dr. Olitzky of New York, who is also down with typhus, is reported to be recovering.

Mosquito Week.—The Department of Health of New York City announces that the week beginning May 1, is to be set apart as "mosquito week," and that during that time a determined war will be waged against the pests. This was decided upon at a conference held last week at the Health Department between the local authorities and representatives of the health boards of Nassau, Suffolk,

and Westchester Counties, New York, and Hudson County, New Jersey. Commissioner Emerson says that the Health Department will prosecute all owners who neglect proper precautions in the drainage of their properties. The Department will also breed for experimental purposes 1,000,000 mosquitoes and will prepare them in glass jars as exhibits to be distributed to the public schools in the summer and used as object lessons in the nature study courses.

Dr. Haiselden Resigned.—Dr. H. J. Haiselden of Chicago, who achieved considerable notoriety last fall because of his refusal to operate on a defective baby, has resigned from the Chicago Medical Society on March 13, on the charge of unethical conduct. His expulsion was recommended by the committee on ethics of the society because he had permitted the publication of a serial story of the case in a newspaper over his signature and had posed for moving pictures.

"The Medico-Legal Journal" has changed hands, Mr. Clark Bell, its founder and publisher, retiring, and being succeeded by Dr. Alfred W. Herzog as editor and publisher. The journal will appear henceforth as a monthly instead of a quarterly.

Help for Drug Addicts.—The Board of Inebriety of New York has, with the cooperation of the Commissioner of Charities, obtained additional facilities at the City Hospital and the Kings County Hospital for the preliminary treatment of drug addicts who are afterward to be cared for at the Farm Colony at Warwick. In addition to the hospital and industrial colony at Warwick, which is now being enlarged so that it will be possible to accommodate 300 patients by the end of the year, the Board of Inebriety is empowered by the law to provide for the treatment in the city of alcoholics and those suffering from drug addiction.

Negro Dies at 121 Years.—Louis Merriman, a negro of Kansas City, Mo., who was said to have been born 121 years ago, when Washington was President of the United States, died recently at his home.

Hospital Reports.—The Roosevelt Hospital, New York, during the year ending December 31, 1915, treated 33,918 patients, according to the forty-fourth annual report of the hospital recently issued. Of these, 4,826 were cared for in the wards, 12,625 in the emergency department, and 16,467 in the outpatient department. Since the opening of the hospital on November 2, 1871, treatment has been given to 130,283 bed patients; 936,250 ambulance cases have been cared for, and 2,186,125 patients have been seen in consultation. For the year just ended, the total disbursements of the hospital are given as \$412,673.34.

The annual report of the Flower Hospital, New York, covering the year ending September 30, 1915, states that during that time 4,749 patients were cared for in the hospital, of whom 1,189 were free patients, and 1,401 city patients. The total days of treatment were 50,605. The hospital ambulances answered 5,671 calls, an average of over fifteen a day, during the year. In the dispensary, 27,417 treatments were given and 20,529 prescriptions filled.

The Northern Dispensary, New York, during 1915 treated 12,327 patients in the dispensary and 1,678 in their homes, 6,495 of the total number being children under fifteen years of age. The number of cured or relieved patients was 12,137. The total disbursements for the year were \$10,272.55.

Field Hospital Review.—The First Field Hos-

pital, N. G. N. Y., the only organization of its kind in New York City, and the first in the United States, was reviewed on the evening of March 14 by Lieut.-Col. W. S. Terriberry, chief surgeon of the National Guard of New York. The organization was formed ten years ago and is reputed to be the most efficient in this country.

To Study Tuberculosis.—The Association for the Promotion of Medical Research for the Prevention and Cure of Tuberculosis was recently incorporated in New York State. Its chief office is in New York City and its field of labor is the United States; its purposes are set forth as the establishment of professorships and scholarships in the various medical schools and the maintenance of institutions for the treatment of tuberculosis.

State Psychopathic Hospital.—If the Wheeler bill, creating a clearing house for the mentally deficient in New York State is passed, it has been stated, a number of wealthy and public spirited citizens will build in New York City a large psychopathic hospital which will be leased to the State for a nominal amount. It is said that the sum of half a million dollars has already been pledged for this undertaking. The Wheeler bill creates a commission of seven persons with an executive manager to supervise the work of examining and diagnosing the cases of the mentally deficient and to investigate the causes of mental deficiency.

Measles at Training Station.—The outbreak of measles at the Naval Training Station in Newport, R. I., is now said to be well under control. Twenty-two patients were being cared for at the Naval Hospital on March 12.

In Aid of Bellevue.—By an arrangement between one of the large New York department stores and the Social Service Committee of Bellevue Hospital, a number of society women, members of the committee, acted as saleswomen in the store during the week of March 13, 10 per cent. of their sales being donated to the hospital.

Montclair a Baby Town.—In connection with the recent observance of Baby Week in Montclair, N. J., announcement is made that during 1915 the death rate of infants under one year of age in Montclair was 65 per 1,000 births, as compared with 123 per 1,000 for the State of New Jersey, 124 for the United States, 160 for Japan, 192 for Germany, and 332 for Chile. The deaths from diarrheal disease of children under two years of age in Montclair decreased from 131 per 100,000 of population twenty-five years ago to 12 in 1915; while the number of deaths of children under five years of age decreased from 500 per 100,000 of population twenty-five years ago to 163 in 1915.

Chicago Death Rate.—During the week ending March 11, there were reported in Chicago a total of 767 deaths, giving an annual death rate per 1,000 of 16.1, as compared with a total of 847 deaths for the same week of last year, when the rate was 18 per 1,000. The largest decreases were noted in the deaths due to tuberculosis, which dropped from 91 last year to 61, and to pneumonia, which dropped from 141 to 102.

The Harvey Society.—The ninth lecture of the series will be held at the New York Academy of Medicine, 17 West Forty-third Street, on Saturday evening, March 25, 1916, at 8.30 p. m., by Dr. R. T. Woodyatt, University of Chicago. Subject: "On Intermediate Carbohydrate Metabolism."

Gifts to Charities.—By the will of the late Mrs. Mary Van Nest Jackson, who died recently, St.

Mary's Free Hospital for Children, New York, receives a bequest of \$80,000, and St. Luke's Hospital, New York, one of \$25,000.

St. Joseph's Hospital, Yonkers, receives \$10,000, and the German Hospital and the Knapp Memorial Hospital, \$5,000 each, by the will of the late Mrs. Mary A. Halloran of this city.

The Rice Memorial.—Announcement has been made of the purchase, from the trustees of Cornell University, of the Guiteau estate at Irvington-on-Hudson as the site for the Isaac Rice Memorial Hospital, which will be built by Mrs. Rice as a convalescent home and rest cure for patients from New York. The property consists of about fourteen acres, offering ample space for the four buildings which it is proposed to erect, at an estimated cost of \$300,000; these comprise a main structure containing 100 beds and a number of private rooms, a nurses' and servants' home, an administration building, and a power house. As previously announced the new hospital will co-operate especially with the Beth Israel Hospital, New York, and will receive patients without distinction of race or creed.

New Cancer Hospital.—In addition to several smaller bequests to New York hospitals, the will of the late Mrs. Mary A. Halloran of this city, provided for the gift of approximately \$300,000 to the Sisters of Charity of St. Vincent de Paul for the establishment at Stanford, N. Y., of the "Halloran Cancer Hospital," as a branch of St. Vincent's Hospital, New York. The property owned by Mrs. Halloran at Stanford is left as the site for the hospital.

Personals.—Dr. Isadore Dyer, dean of the medical college of Tulane University, appeared recently before the Senate Committee considering the establishment of a national leprosarium.

Dr. Simon Flexner of New York has been appointed Cutler lecturer at the Harvard University Medical School for this year.

Dr. Daniel J. McCarthy, professor of medical jurisprudence, and Dr. Alonzo E. Taylor, professor of physiological chemistry, University of Pennsylvania, Philadelphia, have been appointed special attaches to the American Embassy in Berlin, to aid in Red Cross work in Germany.

Dr. John E. Daugherty, formerly a member of the Indian Service, has been appointed medical superintendent of the Greenpoint Hospital, Brooklyn, which is under the control of the New York Department of Charities.

Dr. Clarence W. Wille, surgeon in command of the United States Marine Hospital at Cleveland, Ohio, has resigned his position and will take up the practice of surgery in Cleveland.

Dr. Don Cleveland of the Royal Victoria Hospital, Montreal, has received a commission in the Royal Army Medical Corps, and will shortly leave for England.

Obituary Notes.—Dr. NATHAN GROSS BOZEMAN of New York, a graduate of the College of Physicians and Surgeons, New York, in 1885, died at his home, from pneumonia, on March 17, aged 61 years. After his graduation from the medical school Dr. Bozeman served as an interne at the Woman's Hospital, New York, and also studied abroad in Coburg, Paris, and Vienna. Since that time he had practised in New York, and at the time of his death was attending gynecologist at the Northeastern Dispensary, the Bayonne Hospital, and the Hackensack Hospital, and a member of the American Medical Association, the New York State and County Medical Societies, the Greater New York Medical Association, the

Lenox Medical and Surgical Society, and the Woman's Hospital Society.

Dr. ROBERT ALLEN BLOOD, formerly of Boston, a graduate of Harvard University Medical School in 1870, and a member of the Massachusetts Medical Society and the District Society, died at his home in Lake Sunapee, N. H., suddenly, on February 21, aged 78 years. Dr. Blood was at one time surgeon general of Massachusetts, and at the time of his death was president of the Association of Military Surgeons of the United States.

Dr. JOHN A. DICKES of Portland, Ind., a graduate of the Kentucky School of Medicine, Louisville, in 1885, and a member of the American Medical Association, the Indiana State Medical Association, and the Jay County Medical Society, died at his home from heart disease on February 28, aged 58 years. Dr. Dickes had served as secretary to the County Board of Health for a number of years.

Dr. AUDRIM T. GREER of Abbeville, Miss., a graduate of the Memphis Hospital Medical College, Memphis, Tenn., in 1892, died suddenly in Holly Springs, Miss., on February 24, aged 56 years.

Dr. EDWIN LANDIS DETWILER of Herndon, Va., a graduate of the Jefferson Medical College, Philadelphia, in 1886, and a member of the Medical Society of Virginia and the Fairfax County Medical Society, died suddenly on February 29, aged 56 years.

Dr. EDWARD LLEWELLYN CRANDALL of Troy, N. Y., a graduate of the Albany Medical College in 1881, died at his home on March 6, aged 60 years.

Dr. GEORGE HUNTINGTON, a graduate of the College of Physicians and Surgeons, Columbia University, New York, in 1871, and a member of the American Medical Association, the Medical Society of the State of New York, and the Dutchess County Medical Society, died recently at Cairo, N. Y., aged 66 years.

Dr. CHARLES HENRY MITCHELL of Lynn, Mass., a graduate of the College of Physicians and Surgeons, Boston, in 1893, died at the Lynn City Home on March 2, aged 69 years.

Dr. THOMAS HENRY MANN of Bolton, Conn., a graduate of the Albany Medical College, Albany, N. Y., in 1870, and a member of the Rhode Island Homeopathic Society, the American Institute of Homeopathy and the Connecticut Homeopathic Society, died at his home on March 3, after a long illness, aged 73 years. Dr. Mann was for years interested in journalism. He was one of the founders of the *Milford Daily News*, Milford, Mass., and later was editor of the *Fitchburg Evening Mail*.

Dr. WILLIAM C. BOUTON of Waukegan, Ill., a graduate of the Northwestern University Medical School, Chicago, in 1889, and a member of the American Medical Association, the Illinois State Medical Society, and the Lake County Medical Society, of which he had been secretary, died at his home on February 29, after a long illness, aged 51 years.

Dr. AMBROSE M. KEIM, a graduate of the Jefferson Medical College, Philadelphia, in the class of 1877, died recently at Bethlehem, Pa., of heart disease, aged 62 years. Dr. Keim was for twelve years coroner of Northampton County, and was a member of the Medical Society of the State of Pennsylvania and the Northampton County Medical Society.

Dr. EDWARD W. ROOS, formerly of Buffalo, N. Y., a graduate of the University of Buffalo Medical Department in 1903, died recently at Corning, N. Y.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

HUNTERIAN LECTURE, ROYAL COLLEGE SURGEONS—
ULCERS, NEW AND OLD—PYLORIC-JEJUNAL OP-
ERATIONS.

LONDON, Feb. 25, 1916.

SIR J. BLAND SUTTON took for the subject of his Hunterian Lecture at the Royal College of Surgeons "Ulcers, New and Old: Jejunal for Duodenal Ulcers." On the outset he remarked that fifty years ago chronic duodenal ulcer was recognized as a clinical entity, and its treatment long remained in the physician's province. Operations were performed for it in 1893 and two following years, and in the present century a new field of surgical enterprise has been opened up. For some unknown reason the ulcer in the great majority of cases is on the anterior wall of the duodenum, within 2 cm. of the pylorus; it is not often accompanied by physical signs but the symptoms are distinct and easily recognized. The ulcer often appears as a simple roundish depression in the mucous membrane—the muscular coat its floor. In other cases a layer of thickened peritoneum forms the base; or it may rest on the pancreas, liver, or gallbladder. If on the anterior wall of the duodenum it may rest on the peritoneum of the anterior abdominal wall. Ulcers near the pylorus frequently cause obstruction by the edema of the mucosa. Duodenal ulcer does not become cancerous although it is one of the most chronic forms of ulceration and generally occurs at the age most liable to cancer. Sir Bland Sutton said he had long sought among the living and the dead and in museums for a duodenal ulcer that had become cancerous, but so far his search had "been unavailing." So, too, he found the frequency with which gastric ulcers become cancerous and the infrequency of such change in the duodenum was difficult of explanation. In gastric cancer small detached fragments are transported into the small intestine but implantation above the ileocecal valve is unknown. The lecturer agreed with Shattuck that they would not escape tryptic digestion.

Jejunal ulcer following gastrojejunostomy is often called peptic ulcer, is dangerous, sometimes perforates before protective adhesions have been formed and causes septic peritonitis which in turn is fatal: or this ulcer may have thickened edges and run a chronic course. It causes pain aggravated on taking food, often tenderness and sometimes distinct swelling under the upper part of the left rectus muscle, indicating that the peritoneum on the anterior abdominal wall is involved. Sir Bland had been able to study the changes preceding the ulcer in the duodenum and exhibited one of the specimens.

It is the common opinion that duodenal ulcer is caused by the acid chyme ejected through the pylorus on to the duodenal wall. Bacterial action has not been much studied as to this; the stomach is thought to be amicrobial so long as it can expel its contents, but the fluid found in the abdominal cavity in cases of perforated ulcers swarms with streptococci and other organisms. Jejunal ulcer is rarely met with after gastrojejunostomy for cancer of the stomach—perhaps few patients survive long enough for its formation. This operation and others of the indirect kind relieve the patient though they do not remove the disease. The most favorable conditions for it are a pylorus blocked

by an inflammatory mass and a stomach able to propel the chyme through the new opening and prevent its reflux. It cannot be relied on with an unobstructed pylorus, and as it exposes patients to the risks of regurgitant vomiting and jejunal ulcers the lecturer prefers to excise the pylorus and the segment of duodenum containing the ulcer. This excision is not a serious physiological loss. Half the stomach, indeed the whole may be removed; the lecturer himself had removed it for cancer from a woman of 35, who survived 3½ years. She could not eat as big a meal as her husband, she said, a year after the operation, but made up for that by "eating two meals to his one."

There is some uncertainty about the functions of the pylorus; the lecturer believes it is extremely sensitive, though, like the buccal and anal sphincters, this is only proved when it is chapped or ulcerated. When excised it easily admits the index finger, a contrast with preserved specimens in which the orifice is quite small, having contracted under the influence of the preservative fluid. The favorable conditions for operation are narrow, elongated, pyloric segment of the stomach and absence of adhesions to liver, pancreas or intestine. Adhesions are unfavorable and if extensive forbid interference. Sir Bland Sutton's first pylorotomy was in 1909, since when he has performed twenty. In three of these gastrojejunostomy had been previously done. In one the symptoms returned three months after, in a second in six years, in a third in two years. One died on the nineteenth day; the suture line had sloughed in two places. The results of excision are mostly good if the pylorus is obstructed and so the chyme compelled to pass by the new route, but if it can pass through a partially obstructed pylorus it may continue to do so.

2. The End-Results in Seventy Consecutive Cases of Umbilical Hernia Operated upon at the Massachusetts General Hospital.—Channing C. Simmons gives a report of the above cases operated upon between January 1, 1909, and April 1, 1914. During this period he had the opportunity to operate upon all of the cases entering the hospital as a special assignment—fourteen in all. The other fifty-six cases were operated upon by twenty different members of the staff, the largest number done by any one man being seven. The length of time the cases were followed after operation varies from one to four years. Herniæ, if they are going to recur, practically do in less than one year after operation, usually in a few months, so that cases remaining well over one year may be called cured. For purposes of analysis the cases have been divided into three groups according to the type of hernia existing and a description of the operation used by Simmons is given. As a result of the work done and the success obtained Simmons draws the following conclusions: Small umbilical herniæ in thin adults, and umbilical hernia in children, may be cured by any operation which removes the sac and closes the defect in the abdominal wall. Cases of umbilical hernia in stout adults are difficult to cure.

The Mayo operation, of transverse closure of the ring, with an overlap of the aponeurosis, gives the best results. In adults, closure of the ring by any other method than the Mayo, in a general hospital, is followed by 46.4 per cent. of recurrence. Recurrence, if it is to take place, usually does so in less than one year. The suture material employed has no relation to the liability to recurrence. Skin sepsis is very likely to occur, but, apparently has no relation to recurrence.

3. **Some Electrocardiographic Studies of Patients under Digitalis Treatment.**—Harold W. Stevens made the observations upon this series of patients while working as a fourth year student in the medical wards of the Peter Bent Brigham Hospital, Boston. The purpose was to study the variations of the individual electrocardiogram during the course of digitalis treatment, and, if possible, to determine which variations may be related with the effect of the drug. Patients were chosen so that the group includes the common types in which digitalis treatment is usually considered as indicated, which were two cases of auricular fibrillation, two cases of auricular flutter, one case of paroxysmal tachycardia, and three cases with normal rhythm, but showing evidence of myocardial weakness. The conditions of observation were such that it did not seem feasible to limit the study to cases receiving digitalis alone, consequently several of the patients at some time during the period of study received other drugs, none of which is recognized as having any definite cardiac effect. Successive electrocardiographic tracings of individual patients were made as frequently as it seemed that a record would be significant, the interval varying from one to several days. Eight tables containing data of the electrocardiograms accompany the report, and Stevens from these observations has obtained the accompanying summary: 1. The cases in which digitalis produces marked slowing of the heart are cases of abnormally rapid rate; the drug in ordinary doses appears to have little or no effect upon rates which are normal. The ventricular slowing may be produced in cases of normal auriculo-ventricular sequence and in cases of auricular fibrillation and auricular flutter. 2. In some cases of normal rhythm under digitalis treatment there is a distinct increase in the P-R interval; and an accompanying increase in the R-T interval. In some cases of fibrillation also the increase in the R-T interval is found. In most instances these increases are coincident with a decrease in the rate and hence accompany an increase in the length of the whole heart cycle. A possible factor in the improvement of the heart's action under digitalis may be the increased mechanical advantages resulting from the increase in the total length of the cardiac systole. 3. A single case in which digitalis coupling occurred shows, in all instances of the extra systoles, complexes of the same type, indicating a common focus of origin. 4. A single patient showed a much increased susceptibility to slowing by vagus pressure during the digitalis treatment. The P-R and R-T intervals referred to stand as "time 50th sec." in the tables and represent together the length of the heart beats.

1. **The Psychology of the Physician as a Wage Earner.**—Charles W. Burr, MEDICAL RECORD, Feb. 26, 1916.)

2. **The Conservative Treatment of the Tonsils.**—G. Hudson-Makuen places himself on record as a conservative radical, or as one who believes in the exercise of great care, and in the acquirement of great skill, in the performance of this exceedingly difficult and important operation for the removal of tonsils or any of the adjacent structures; also when it comes to a question of diagnosis and the necessity for the removal of tonsils. The question arises, what is a conservative treatment of the tonsils? The answer is that it may be regarded as including any medical or surgical treatment that falls short of their complete enucleation. Improvement of drainage of the tonsillar region, in the case of diseased conditions by the opening up of retention pockets, whether they are found in the crypts of the tonsils themselves or between the tonsils and the adjacent faucial pillars, gives relief and in many cases cure. Hudson-Makuen considers that the faucial tonsils rarely become foci of serious general infection and in the great majority of cases radical operation is not indicated. If the operation be absolutely indicated, the tonsil should be removed with as little as possible of the surrounding tissue and as little as possible of the so-called capsule itself. Hudson-Makuen further states his views: In its normal state the tonsil is not a menace, but a probable protection, and its presence is helpful in both phonation and articulation. The fact that we do not know the systemic and mechanical functions of the tonsil is an argument in favor of conservatism rather than radicalism in our treatment. The enucleation of the tonsil is the simplest and most expeditious way of dealing with it, but that it is the best way is always a matter of opinion and a question for careful consideration in each case. It is easier to remove a tonsil than it is to know whether or not it should be removed, and the very simplicity of the operation and its apparent freedom from untoward results make the temptation all the greater to do it rather than resort to the more difficult but less radical and probably better methods. In our clinics the temptation to remove tonsils in a somewhat wholesale manner is almost irresistible, but the practice is none the less reprehensible. It is obvious that dispensary cases should have the same careful treatment and the same consideration that are given to the most deserving private cases, and lack of time in our dispensary work is not a good excuse for ill-advised and careless operations. The man who tonsillectomizes a dozen or fifteen patients in a single afternoon had better spend his afternoons in the abattoir. However, after all is said and done against radicalism in tonsillar surgery, the fact remains that in certain selected cases there is nothing we can do that gives such brilliant results as the removal of the tonsils and adenoids, and in well selected cases there can be no objection to the operation, provided always that it is carefully performed. The very brilliancy of these results, however, has an element of danger in that it leads us to make the radical operation the rule, rather than the exception which it ought to be, and, as has been said in a previous communication, the tendency of the future will be to find out, not how to operate, but how not to operate, or at least how to operate in the most conservative manner.

6. **Spastic Paralysis in Children.**—Jacob Grossman gives a report of seven cases of this condition, due to injury, birth conditions, syphilis, etc. Paresis and spasm are given as the characteristic features of cerebral hemiplegia while sensory disturbances are rare and when present are confined mostly to the hands. Mus-

cular hypertrophy occurs when the spasticity is very great and is usually due to overwork of the muscles. A peculiar phenomenon of hemiplegia is seen in the posthemiplegic motor disturbances, which occur frequently. It may be expressed in tremor, or in its severest form, may consist of permanent tremor, chorea, or athetosis. Under treatment he states that there is no cure for cerebral palsy. Cases that respond to iodine and mercury are to be suspected; the symptomatic treatment consists of massage, electricity, etc. He views these conditions from the following conclusions: 1. Spastic paralysis may result from an apparent normal delivery. 2. In some cases interference with the dressing or the bathing of the infant may be the first evidence of an existing spastic paralysis. 3. In other cases delayed functions of sitting and walking directs one to the existing spastic paralysis. 4. Convulsions in infants, either immediately after or shortly after delivery, should make us suspicious of cerebral injury. 5. The possibility of syphilis as the etiological factor in some cases of spastic hemiplegia must always be remembered. 6. Where ophthalmoscopic examination reveals increased intracranial pressure, and where there is not a great amount of interference with the mentality of the patient, subtemporal decomposition, as described by Sharpe, should be performed. 7. In the other cases, and in the after-treatment of cases operated in, massage, electricity, manipulation, supports, tenotomies, and muscle education usually offer relief to the patients, and influence to a certain degree the existing condition.

5. A Study of the Etiology of Chronic Nephritis, and of the Efficiency of the Phenolsulphonophthalein Test.—Brown and Cummins state that among 7,000 cases the initial urine examinations showed that 594 patients had albumin and casts, although only thirty-eight of them were admitted as cases of nephritis. These 594 cases were divided into two groups: those in whom the blood pressure, in absence of any other obvious cause, was above the maximum normal while at rest in bed on ordinary hospital diet, and those in whom it was normal or below. Each group was studied with reference to entrance diagnosis, complications, age, occupation, use of alcohol, and previous infections. The cases with a blood pressure above 180 were separated from the cases with high blood pressure. It was not possible to distinguish in all high blood pressure cases between chronic interstitial nephritis and arteriosclerotic

kidney, and they will be considered as chronic interstitial nephritis. It is obvious that the diagnosis of nephritis from the results of the tables given is practically a laboratory diagnosis, that it exists as a complication undiscovered until some other condition brings the patient to the hospital. The chief difference between the two groups lies in the fact that in the high blood pressure cases three-fourths were over forty years of age, whereas in the normal or low blood pressure group less than one-third were above the age of forty. Thus the incidence of marked permanent structural change in the kidney bears a distinct relation to age. Both groups show that venereal disease and infection from the scarlet fever group were nearly two times more frequent than in normal kidney cases which makes the supposition reasonable that the signs of kidney irritation in the low pressure group portend a likelihood of future kidney insult and change not evidenced by the control group. From the tables given it is seen that certain of the infectious diseases, notably the venereal and scarlet fever groups, were from twenty to three hundred per cent. commoner in the early history of chronic nephritic cases than in the non-nephritic cases. The influence of alcohol played a less prominent part as an etiologic factor than was formerly supposed. In the nephritic and non-nephritic kidney conditions, alcohol was used in from sixteen to twenty-five per cent. more cases than in the control group. A previous history of some diseases other than the minor children's ailments was about twice as common in the nephritics. In cases of streptococcus infection, especially in the throat, they have been surprised to find streptococci in the urine with very little evidence of kidney disturbance, often enough to warrant them in believing that the beginnings of many serious kidney disturbances are insidious. With reference to the laboratory methods in urine examination phenolsulphonophthalein seems to give the best results. Brown and Cummins make their observations as follows: Following the technique as described by Rowntree and Geraghty, sixty-seven patients were studied with the phenolsulphonophthalein test, and seventy-five injections were made. Of the sixty-seven patients, thirty-six (50 per cent.) were nephritics, one with acute parenchymatous nephritis, thirteen with chronic parenchymatous nephritis and twenty-two with chronic interstitial nephritis. Of the non-nephritic group, the average excretion for two hours was 51.4 per cent. The lowest was 35 per cent. in a case of lumbrosacral myalgia and no demonstrable signs of nephritis. Two cases of neurasthenia showed 35 per cent. The highest percentage was seventy-seven in a case of cholelithiasis.

6. Analgesia and Anesthesia in Obstetric Practice.—Arthur J. Skeel says that for two or three years the attention of obstetricians in this country has been called rather sharply to methods of relieving the pain of labor. Since November, 1914, he has employed gas for the relief of pain in seventy-two labor cases. He outlines the indications and contraindications for the use of morphine, nitrous oxide and oxygen, and ether, and also his routine in handling a normal labor. His indications for morphine during the first stage are: A rigid, hypersensitive os; evidence of considerable pain with a probable first stage of several hours, as in most primiparas; the presence of nagging but ineffectual pains which irritate and exhaust the patient out of all proportion to results. Patients in whom ineffective uterine action, true primary uterine inertia, seems to be the cause of the delay are not given morphine. Gas is begun at the beginning of the second stage, or if the patient suffers severely, shortly before dilatation is completed. Administration is begun with small amounts,

as thirty gallons of nitrous oxide to fifteen gallons of oxygen. As the head approaches the pelvic floor and strikes the perineum, the nitrous oxide is increased to fifty or sixty gallons. This is further increased to seventy to eighty gallons as the perineum distends. When the head is born the gas is at once discontinued and the patient sharply revived by a few whiffs of pure oxygen. The following remarks sum up his conclusions: I wish to enter a vigorous protest against the advice at present being so freely given that any one may use gas in labor cases with perfect safety. Gas is a powerful therapeutic agent with infinite possibilities for harm at the hands of incompetent or careless users. The statement has been made and is, I believe, accepted, that gas in the hands of an expert is a safe anesthetic, but the most dangerous anesthetic if given by a novice. Of course this is far too strong a statement to make concerning analgesia. Even here, however, some knowledge and experience are necessary to secure both safety and satisfaction from its use. Moreover, the temptation to follow a gas analgesia labor with a gas anesthesia for repair is so obvious that I would earnestly urge all those expecting to adopt this method to spend sufficient time in special study of the agents he is to use, so that he can direct its administration. This does not mean that a doctor must equip himself as a gas expert. The skill necessary for its use in labor can be acquired in a short time, but free use of gas by the absolutely inexperienced will surely lead to tragedies.

8. The Treatment of Diphtheria Carriers with Iodized Phenol.—William O. Ott and K. A. Roy announce that the cases reported consist of carriers convalescent from clinical diphtheria in the infectious ward of the Charity Hospital, New Orleans, and some that did not have diphtheria but were persistent carriers. In all cases reported iodized phenol (acidum carbolicum iodatum of the N. F.) was used. It contains 60 per cent. phenol (carbolic acid), 20 per cent. iodine crystals, and 20 per cent. glycerin. In pharyngeal cases, the tonsils, uvula and posterior wall of the pharynx were swabbed every forty-eight hours until negative cultures were obtained. In nasal cases, the entire anterior part of the nasal cavity was swabbed with iodized phenol every forty-eight hours. Care was taken not to allow the preparation to run over the face or drop into the larynx. Cultures were always made a few minutes before the local application. In this way, forty-eight hours elapsed after each application of iodized phenol before another culture was made. Seventeen cases were treated. Negative cultures were obtained after one application of iodized phenol in six cases (35 per cent.); after the second application in five cases (29 per cent.); after the third application in two cases (12 per cent.); after the fifth application in one case (6 per cent.), and after the sixth application in two cases (12 per cent.). One case (nasal) was under treatment for twenty-one days and required nine applications before negative cultures were obtained. With the exception of this case, none of the other sixteen were under treatment longer than eleven days.

15. The Function of the Thyroid-Parathyroid Apparatus.—Edward C. Kendall of the Mayo Clinic, in formulating and presenting a hypothesis of the function of the thyroid-parathyroid apparatus gives Plummer's basic hypotheses with reference to the effects of the thyroid gland disturbances: (1) In thyroid disturbances the effects are due to a change in the rate of a normal function. (2) The stimulating effect of increased thyroid activity is not felt in any particular set of organs or tissues alone, but the stimulus is active throughout the body. (3) The stimulating action is intracellular. With

this basis he goes on to state that when protein is catabolized in the body, nitrogen is not excreted as ammonium carbonate, but appears chiefly in the form of urea. Some mechanism must exist for the conversion of the ammonium carbonate resulting from deamination into urea. After parathyroidectomy the ammonium content of the urine is increased, and it has been suggested that tetany following this operation is due to this increase in ammonia. The acid radical to which the ammonia is attached has not been determined, but it has been shown that the soluble salts of barium, strontium, calcium, and magnesium relieve tetany following the above operation, and also that tetany is controlled by the injection of acids. (Wilson.) The only ammonia salt that can react with all five of these reagents forming a non-toxic compound is ammonium carbonate. From other investigators' results, and his own Kendall suggests that the function of the parathyroid is to convert ammonium carbonate into urea. The above suggested principles furnish a means for the study of the factors controlling the activity and the manifestations of animal life. The process occurring in the normal animal may be outlined as follows: The body proteins are decomposed to a slight extent into amino acids. Under proper conditions and in the presence of the iodine compound these are deaminized, and the products are then burned either directly into carbon dioxide and water or are used for the formation of carbohydrates, fats, etc. If an increase in the amount of the iodine compound in the cell is brought about, the speed at which this reaction takes place is increased, the equilibrium between proteins and amino acids is disturbed, more amino acids pass into the reaction, and finally, the proteins, unless replenished, are exhausted. At the same time the products of the reaction, deaminized acids, are formed in increased amounts. This results in an increased speed of the processes of oxidation and the formation of carbohydrates and fats. There is no direct change in the mechanism entering into the metabolism of carbohydrate and fat formation and oxidation. The only thing which is influenced is the rate at which deamination occurs. If the thyroid secretion is the catalyzer controlling the rate of deamination of amino acids, and the parathyroid furnishes the mechanism for the conversion of the so formed ammonium carbonate into urea, then urea (and ammonia) output by the body is within certain limits a measure of thyroid-parathyroid activity. If this hypothesis be correct, we may conclude that the function of the thyroid is to furnish a catalyzer which regulates the rate of deamination. This is an outline of the function of the thyroid-parathyroid apparatus under normal conditions. Under the effects of excessive secretion, the presence in the cells of an increase of the iodine compound produces a condition similar to that found during violent exercise. An increase of from 200 to 300 per cent. in the rate of metabolism has been found in cases of exophthalmic goiter. This is at a temperature, but slightly above normal, and it is apparent that the usual controlling mechanism for temperature regulation is not broken down. At death from this condition, a crisis is often seen in which the controlling mechanism does break down, the temperature reaches 106° or more, and metabolism runs wild. The other extreme is myxedema. Here metabolism is at a minimum. The entire absence of iodine compound from cells would mean a metabolism at zero rate—death. The life and activity of every individual cell is dependent on the amount of the iodine compound in it. It is obvious that during different periods of rest and activity the organs require varying amounts of the iodine compound. Therefore, it

can be assumed that the function of the thyroid is not only to elaborate this substance, but also to supply the cells of the body with the amount necessary to meet the momentary demands of each cell. After cell activity has been heightened by an increase of the amount of the iodine compound present, there must be some mechanism for the subsequent removal of some of the catalyzer from the cells and for carrying it back to the thyroid, there to be held again until needed. The vehicle for carrying the iodine compound from the gland is probably the colloid found in the thyroid secretion. It is suggested that the balance between free amino acids and colloid may be the mechanism governing the supply and demand for the catalytic substance. The presence in the blood of abnormal amounts of amino acids may be a stimulus to the activity of the thyroid. If the foregoing hypotheses of the function of the thyroid-parathyroid apparatus proves tenable, Kendall states that its application to the explanation of biological phenomena is apparent, but further elaboration of the hypothesis will not be attempted until after a quantitative study of the factors involved.

1. **The Lettsomian Lectures on the Effects of High Explosives upon the General Nervous System.**—Fred. W. Mott delivered this lecture before the Medical Society of London on February 21. Under the symptoms of CO poisoning, he states that the action of CO is most marked upon the central nervous system, and that a very important symptom is loss of memory sometimes coupled with loss of recognition. A detailed account of the histological changes in the brain in CO poisoning, shell shock, and spinal concussion is given, showing the histological similarity produced by these conditions. Individuals are classified according to their mental and bodily condition at the time of shock as follows: 1. Inborn. 2. Acquired: due to alcoholism, syphilis, or previous head injury; a lowered neuropotential; nervous exhaustion from various causes; bodily exhaustion from cold, wet, fatigue, and hunger. From the 156 cases studied, a large majority of so-called shell shock cases admitted into the hospital with functional neurosis in some form, occurred in individuals with a nervous temperament, or with an acquired or inherited neuropathy. In a certain number of cases the cumulative effect of active service had produced a neurasthenic or hysteric condition in a potentially sound individual. Among the large number of officers Mott has seen sent back on account of neurasthenia, none have exhibited symptoms of functional paralysis or mutism. Cases which were supposed to have developed epilepsy as a result of shell shock were, usually, individuals who were either epileptics or potential epileptics prior to the shock. For ten years Mott has studied the subject of hereditary predisposition of epilepsy and insanity, and his results convince him that this condition is the one in which an inborn tendency is shown more than any other nervous affection. Shock may be an exciting cause, but is not *per se* the cause of epilepsy. This is important because a man may know that if he can claim

that he is an epileptic his services will be no longer required, and he can state that the shell shock was the cause and claim a pension for being incapacitated by active service. Evidence goes to prove that an acquired or inborn tendency to neurosis plays an important part in the effects on the central nervous system of exposure to shell shock in a majority of cases.

3. **Paratyphoid Fever: Its Clinical Features and Prophylaxis.**—William Henry Willcox gives an account of this condition based on the clinical study of a large number of cases in the Dardanelles area. No less than 150 cases of the enteric group yielded a positive result by cultivation from the blood. Of these 13.5 per cent. were typhoid cases, and 86.5 per cent. were paratyphoid cases. This change in ratio of percentage of paratyphoid to typhoid cases in the Mediterranean area is in itself one of the most striking illustrations of the prophylactic value of antityphoid inoculation. He divides his cases into three groups: 1. Those with sudden onset and characteristic symptoms, the commonest type. 2. The mild cases. 3. Severe toxic cases closely resembling true typhoid. The symptoms of each group are given, but are too numerous to be given here. The mortality is between 3 and 5 per cent. Willcox considers that with reference to mortality and risk to life, paratyphoid A and B are decidedly more serious than is usually supposed. Early recognition of the disease, bacteriological investigation for the early diagnosis of cases and for the recognition of carriers, and general preventive measures are the best prophylactic measures. Individual protection of the men by prophylactic inoculation is now being carried out by the War Office. Most important measures are: (1) Protective inoculation of the personnel of hospitals against paratyphoid as well as typhoid. (2) When reinoculation of troops is necessary a mixed vaccine protective against paratyphoid A and B as well as against typhoid should be given. (3) The inoculation of troops with a mixed vaccine before going abroad.

5. **Notes on Albuminuria and "Trench Fever."**—F. G. Chandler states that from the beginning of the war he has seen in France hundreds of cases among the soldiers of pyrexia of sudden onset, all almost exactly similar and presenting symptoms of influenza. His observations were imperfect as a cellar or a dugout formed a consulting-room and one and one-half test tubes, together with some acetic acid comprised his laboratory outfit. The symptoms shown in these men were temperature 102° to 103° F., pyrexia, pain and stiffness of limbs, vomiting or nausea, headaches, and severe pain in the back; hematuria, hemoptysis, hematemesis, presence of blood in the stools, and sometimes albumin in the urine. The temperature fell to normal in two or three days, after which there was a residual weakness and pallor. Herpes labialis et nasi was very common. The treatment suggested was a milk diet as far as possible and detention at some farmhouse. Chandler believes that aceto-salicylic acid and quinine proved of value, with an initial dose of Dover's powder. Dry cupping gave relief for intense backache. These cases of even severe pyrexia soon recover, but if they pass unrecognized, may cause great anxiety to the medical attendant by presenting without apparent cause grave symptoms of renal disorder.

1. **The Epidemic Jaundice of Campaigns.**—William Henry Willcox studied this condition in the Mediterranean region and also among the soldiers of the Expeditionary Force in France during the early part of the war. He states that jaundice is of common occurrence among troops on campaign, therefore it is a disease of importance from the military point of view on account of the amount of incapacity for duty it occasions. The epidemic jaundice of campaigns appears to start as a gastrointestinal infection, the inflammatory catarrh being most marked in the duodenum. At this stage pyrexia and toxemia occur, but there is no general blood infection usually, since blood cultures have been negative. Fortunately, most cases clear up at this stage. The specific organism which is the cause of this condition has yet to be isolated; the contributing causes are chiefly from infection from food, water, and flies. Corresponding care in these directions is necessary, together with notification of jaundice cases in order that immediate preventive measures may be instituted. The treatment consists of rest in bed during the early stage. Liquid diet, which would mean milk on a campaign, together with lemon juice to counteract the lack of vitamins produced by the boiling of the milk. When possible, porridge, mashed potatoes, and vegetable soup may be added. Excess of protein should be avoided. Urotropine gr. x given three times a day produces a gastrointestinal antiseptis. Calomel is contraindicated in repeated doses, since patients suffering from epidemic jaundice are very susceptible to the effect of calomel thus given.

3. **Treatment of Kala-Azar (Indian Form).**—Rogers and Hume have successfully treated this condition by intravenous injections of tartar emetic and by inunctions of metallic antimony. The technique is that usually employed in intravenous work, a 10 c.c. serum syringe being used. The median basilic or cephalic vein is selected. Great care should be taken that the injection is made into the vein and not into the surrounding tissues, as tartar emetic is very irritating, and irritation or sloughing of the tissues may result. The dosage begins with only one-half to one c.c. of the 2 per cent. solution of tartar emetic, but it can be rapidly increased to 3 or 4 c.c. The injection is repeated every two or three days, adding 1 c.c. at each injection up to a maximum of 10 c.c. if there are no marked gastric symptoms. The treatment should be continued until the temperature has remained normal for several weeks with steady gain in weight, and the parasites are found to have completely disappeared from the spleen, and the leucocytes have been raised to about the normal level. It is not necessary to continue until the spleen has been reduced to its normal size, as this will occur after the injections are omitted. In children and nervous women inunctions of antimony ointment, preferably 10 per cent. strength, is worthy of trial, although there is not yet sufficient evidence to prove its absolute value.

5. **Notes on Dysentery Vaccination.**—Castellani considers that dysentery vaccination is of such importance practically, that it is surprising so little attention has been paid to it since the pioneer work of Kruse and Shiga. He gives the following reasons for the limited use of vaccines for this condition: 1. Vaccines containing the Shiga-Kruse bacillus, prepared according to the usual technique give severe local and general reaction. 2. Vaccine prepared from the same bacillus does not give immunity for forms of dysentery due to

Flexner, Flexner-like, and other dysentery germs. Since 1912, Castellani has prepared a mixed dysentery vaccine, and also a vaccine containing the mixed vaccine plus typhoid, paratyphoid A, paratyphoid B. He says that a dysentery vaccine should contain several species of dysentery bacteria and not one only. Vaccine of this character should be prepared with a carbolic salt emulsion from agar cultures without heating, or peptone water cultures may be used. Also it is essential to prepare the vaccine with strains which, though rich in antigen, are not virulent or very little so. A large series of strains of Shiga-Kruse bacillus should be inoculated in rabbits, and the least virulent, provided it be rich in antigen, should be kept permanently as a stock culture to prepare the vaccine. Broth cultures should never be used.

Pancreatic Stone Colic.—Einhorn of New York gives this subject an almost monographic consideration and relates two personal cases. The diagnosis and treatment are summed up as follows: There are periodically appearing colic-like pains in the epigastrium, which set in with transitory attacks of glycosuria. This syndrome is of course not specific for the affection. If, however, the pains disappear suddenly and finally the likelihood of pancreatic stone colic is greatly increased, as suggesting that the stone has reached the intestine. At this period a study of the feces may reveal the presence of a chalky concrement which is devoid alike of cholesterin or bile pigment. The pancreas appears to tolerate the stone for a long time without reaction, but eventually its function is compromised. The transient glycosuria is not always present and hence its absence has no great diagnostic significance. When the presence of an attack of pancreatic colic is surmised, the patient should be placed at rest on a scanty diet. Warm compresses should be applied and if necessary morphine, atropine or both combined should be given as analgesics. After the attack small and frequent meals and alkaline mineral waters should be the diet. If these medical measures do not prevail, and especially if fever develops, trial laparotomy should be performed. Both the biliary structures and the pancreas and its duct should be carefully examined. If there is a stone anywhere present it should of course be removed, but the small size of the pancreatic stone may make it very difficult of recognition. In such a doubtful case the gall bladder should be drained for a time, which often leads to a subsidence of the pancreatitis which has been responsible for the intervention.

Ophthalmological Errors in the Field.—According to Rauch the chances of error in this domain are very numerous. Should dressings be monocular or binocular? It must be remembered that occlusive dressings always lead to retention of pus and tears. In many cases the lid itself is all the protection required. The author mentions such possibilities as dacryocystitis, both before and after the escape of pus. On the other hand, in several lesions of various character a firm occlusive dressing is indispensable. Here belong a corneal injury or foreign body and a unilateral gonorrhea. In blepharospastic affections under certain circumstances, the effects of the sunshine are beneficial, so that the occlusive dressing is contraindicated. Here belong very refractory cases of conjunctivitis. The author cites the case of one patient who also had trachoma. The patients were exposed to the fiercest rays of the sun and complained much at first, but in two weeks blepharospasm had ceased. The severe pains in the eye appear to demand cocaine, but while this drug is an analgesic, it

also irritates the sympathetic nerve fibers, one result of which is mydriasis. In a number of cases the general action on the sympathetic was highly undesirable, and for a mydriatic effect when indicated one should use atropine or scopolamine. The yellow precipitate ointments are apt to be coarse-grained, and the author would substitute some bland preparation, even simple vaseline.

Gas Gangrene.—Conradi and Bieling state that this condition is essentially a disease of war, and in this respect stands almost alone. Against the known disease tetanus one was prepared; against gas gangrene there could have been no preparation. Not that the disease is wholly unknown in peace times. Clinically it is of a uniform type—edema and emphysema about the wound, foamy discharge from the latter, progressive and burrowing gangrene involving the muscles, small rapid pulse, dyspnea and coma. It has not been easy to obtain the offending microorganism in pure culture. The bacillus emphysematodes of Fraenkel is only a collateral find, although it has been looked upon as the cause. The authors in 53 cases have isolated a special germ which they regard as the true bacillus of gas gangrene. It is never found in the blood, but from its predilection to attack the muscles has been termed the bacillus sarcemphysematodes. It exhibits a notable polymorphism and agrees closely with the so-called rauschbrand bacillus of sheep. Special cultures can be inoculated into the muscles of swine and other animals, but in all cultures there is a marked tendency to decrease of virulence, due perhaps to its extreme anaerobic character which renders it very sensitive to the oxygen of the air. In experimental work the muscle is attacked and dissolved while still alive. Along with this property of attacking muscular tissue, the germ causes a sort of cellulitis of the entire limb, characterized by edema and crepitation, with a tendency to hemorrhage. The affected limb also becomes algid. It is evident that differentiation between gas gangrene, gas phlegmon, malignant edema, hospital gangrene and ordinary gangrene as seen in the surgery of the extremities will not be a simple matter in the future, because the microorganisms which produce them should be very closely related. The hospital gangrene of our forefathers has occurred during the present war to a minimal extent.

Gas Phlegmon.—Marquardt has described two cases of this condition. The first one shows that the casual agency of this affection can enter the blood and cause metastatic abscesses and further can carry infection along the lymphatics. In the first case a bullet wound was received through the hip joint. Four days later when admitted to the hospital patient had high fever and delirium. The joint had been shattered throughout. All bony fragments were first removed and a drain inserted. The entire thigh became swollen, and there was elicited not only crepitus but a tympanic percussion note. The wound canal was now thoroughly cleaned out, and incisions were made in the thigh, down to the muscle, with escape of much offensive gas. Incision of the muscles gave the same result. The patient appeared to be doing well when the disease suddenly attacked the leg beneath the affected thigh and at the same time the opposite thigh and the patient soon succumbed. The second patient was wounded in the outer aspect of the left calf with a shell fragment. The affected leg became gangrenous, while a gas phlegmon reached as high as the pelvis. The patient had high fever and delirium. A circular amputation was per-

formed at the lower half of the thigh. As the muscles were divided, much stinking gas escaped. The cellular tissue which should be the seat of a phlegmonous process contained but little gas. After amputation the thigh and hip were incised repeatedly to give exit to gas. Matters at once took a favorable turn and the patient made a good recovery. In contradistinction to gas gangrene there was neither hemolysis nor liquefaction of muscular tissue.

Treatment of Tuberculosis with X-Rays Alone or in Association with the Quartz Lamp.—The present issue contains two articles, the first of which is contributed jointly by Küpferle and Bacmeister and deals with the experimental disease. The conclusions are as follows: In the beginning tuberculosis (experimental) in the rabbit, hard, filtered x-rays can suppress and even cure tuberculosis. The bacillus is not directly attacked but the rapidly growing granulation tissue which naturally under favorable circumstances undergoes cicatrization is stimulated. An optimum dose is required to obtain this effect. Too small doses are inert, while too large doses cause bronchitis and bronchopneumonia. The amount of energy required is from 20 to 23 X of surface energy with reaction intervals of 3 to 5 days' length. Both aspiration and inoculation tuberculosis yield to the treatment. In animal experiment the quartz lamp does not appear to exert any influence in the tuberculous process. The second article is by Bacmeister alone and is devoted to the combined treatment of human tuberculosis with the x-ray and quartz lamp. The case histories of several patients are as follows: 1. Severe left-sided destructive pulmonary phthisis, treated with artificial pneumothorax, total in extent, with unsatisfactory results. Sputum still contained elastic fibers and tubercle bacilli. After two weeks of the combined radiation the character of the sputum improved greatly. After a month's pause the treatment was resumed and maintained for a month or until the sputum was quite negative. Three other cases of similar type are related. Thus far the treatment does not seem to have been tested save in severe, although not hopeless cases, and we can only say that it promises well in all pneumothorax and thoracoplastic cases as after treatment.

Treatment of Bronchial Asthma with the Endobronchial Spray.—Stephan refers to pioneer work in this domain, which is one of a high degree of technique not yet adapted to the general practitioner. Thus far an entire series of complete cures of asthma has been placed on record, to say nothing of those who have obtained material benefit. There is no strong theoretical foundation for this method of treatment, for authors differ widely in their views of the disease. It is possible that the bronchial secretions exert a reflex influence which provokes the spastic crises. But one spray is used—a mixture of novocain and adrenalin, beginning with very small dosage to prevent possible overaction, and increasing slowly until an optimum for the individual is reached. The bronchoscope is invariably used for location of the disease foci. Most of the rami of the second order can be brought into the visual field. For the introduction of the spray an atomizer is used in connection with a suction pump, both devices of Brünings. The former is introduced by the same method as a Kuhn's tube, i.e. without visual control. The author admits that his results are apparently far behind those reported by Ephraim and others. A few patients did very well at first, and in one case there was an interval-free period of nine months.

Book Reviews.

VAGOTONIA. A Clinical Study in Vegetative Neurology. By Dr. HANS EPPINGER and Dr. LEO HESS, of Vienna. Authorized translation by WALTER MAX KRAUS, A.M., M.D., and SMITH ELY JELLIFFE, M.D., Ph.D. Price, \$1. New York: The Nervous and Mental Disease Publishing Company, 1915.

THIS interesting monograph takes up a department of neurology, which has been neglected more or less ever since Langley's great work on the sympathetic nervous system. It is a department too which is bound to become important to the internist, as well as to the neurologist and psychiatrist. The subject is so new that we shall very briefly describe it.

The so-called vegetative nervous system includes all those nerve fibers which go to organs having smooth muscles, such as the intestines, blood-vessels, gland ducts and skin, as well as glands; also to the heart, to each end of the alimentary canal, and to the muscles of the genital apparatus. It differs from the "animal," or sensori-motor nervous system, principally, in having ganglion cells in the peripheral make-up. It is divided into a *sympathetic* system proper and into an *autonomic* system. In the latter the nerve fibers arise from the mid-brain, the medulla, and the sacral cord, and do not come into relation with the sympathetic cord. The sympathetic and autonomic systems are antagonistic, in action, yet both furnish fibers to each organ. The most important nerve of the autonomic system is of course the vagus. Fibers of the vagus go to the heart, stomach, bronchi, esophagus, intestine, and pancreas; while nerves from the sacral portion supply the bladder, anus, genital apparatus, descending colon, and sigmoid. Whether a common nerve center controls both systems is not known. They may be influenced, however, independently, by drugs and physiological stimulation. An irritability or an increased tonus may be thus artificially produced.

The autonomic system has been especially studied in this monograph; and as a result, the authors claim to have discovered a definite symptom complex identified with a state of stimulation of this system. The autonomic system is sometimes spoken of as the "extended vagus." Hence the name, "Vagotonia." We have then instead of our old friend "intestinal neurosis," or neurasthenia, or hysteria of a type, a new friend, a functional autonomic system disease. They say it may be general or local; that the internal secretions are at fault; that it is found most developed in the young constitutional inferior and may bear a relationship to the status thymicus and the lymphatic constitution. The chapters on physiological observations, diagnosis, clinical findings, relations of endocrinous glands to vagotonia, and therapeutic observations are all interesting. The anatomy and physiology of the sympathetic system are of comparatively recent knowledge. The pathology is unknown. The book should stimulate further research along similar lines.

THE DUCTLESS GLANDULAR DISEASES. By WILHELM FALTA, Vienna. Translated and edited by MILTON K. MEYERS, M.D., neurologist to the Lebanon Hospital, and to the dispensaries of the Jewish and St. Agnes Hospitals, Philadelphia, etc., etc. With a foreword by ARCHIBALD E. GARROD, M.D. (Oxon.), F.R.C.P. (London), F.R.S., physician to St. Bartholomew's Hospital, London. With 101 illustrations in the text. Price, \$7. Philadelphia: P. Blakiston's Son & Co.

IN the development of our recent knowledge of the action of the ductless glands, the researches of Falta have been of considerable importance. His studies have been chiefly on the functional activities of the suprarenals and pancreas, but in his monograph, published in 1913, he included all the ductless glands: thyroid, thymus, hypophysis, adrenals, genitals, etc. He included also a section on infantilism, dwarfism, chondrodystrophy, and mongolism, which can not at the present time be definitely correlated with the depression or exaltation of the secretion of any one of the known ductless glands. The work, though very unequal in its original form, certain chapters being filled with valuable information and others being largely compilations of the literature, contained a large amount of material not readily accessible to English readers. The experimental and pathological aspects were not very fully presented, as these were already admirably covered in Biedl's exhaustive monograph. The English translation of Falta's book, therefore, brings to the

large number of physicians who do not read German an extremely valuable clinical discussion of those diseases which, while their pathogenesis is still very obscure, are apparently based upon changes in some way correlated with the functional and, in some cases, anatomical alterations in the group of glands mentioned above. It is much to be regretted that the editor did not fully revise the translation; evidently the person who made the original draft was unfamiliar with medicine, and so a large number of errors have crept in, as an example of which a single paragraph will suffice: On page 220, in the discussion of tetany, the translation reads: "Much difficulty is met with, however, in the diagnosis of pyloric stenosis." While this statement may be true, the original German really states that "the chief difficulty is met with in the diagnosis of the pyloric stenosis"; evidently quite a different meaning. A few lines below, the translation reads: "as the result of gastric lavage during the entire evening," the last words being a wrong translation of *allabendlich*, which means, of course, washing every evening, not all evening. Numerous similar mistranslations occur throughout the text, and should certainly be corrected in another edition, as also should the general style, for while the words are English, the arrangement is often German, and the text is, therefore, extremely difficult to read. The publishers have done their share of the work well, for the mechanical get-up of the book is excellent, the cut reproductions are good, and the type and paper are satisfactory.

THE CRIMINAL IMBECILE. An Analysis of Three Remarkable Murder Cases. By HENRY HERBERT GODDARD, Director of Department of Research, Vineland Training School. New York: The Macmillan Company, 1915.

IN this small volume of 157 pages the author makes an important contribution to the literature of feeble-mindedness on the one hand and that of criminal procedure on the other. The three cases analyzed are regarded as unique in being the first court cases in which the Binet-Simon tests were admitted in evidence, and in which the mental status of the persons under indictment was largely determined by this method. Two of the cases were high grade imbeciles, and these furnish the text upon which the writer makes a plea for a more adequate recognition of the legal irresponsibility of the high grade imbecile. In a chapter on Responsibility the author indicates the difference between *verbal* morality such as the child may have and the deep-seated and appreciated moral principle that develops only with adolescence and experience. Lawyers and jurists will profit by a perusal of this brief for the criminal imbecile.

CANCER OF THE STOMACH, a Clinical Study of 921 Operatively and Pathologically Demonstrated Cases. By FRANK SMITHIES, M.D., Gastro-enterologist to Augustana Hospital, Chicago. With a chapter on the Surgical Treatment of Gastric Cancer by ALBERT J. ÖCHSNER, M.D., LL.D., F.R.C.S., Professor of Clinical Surgery in the School of Medicine of the University of Illinois; Surgeon-in-Chief to Augustana Hospital, Chicago. Price \$5.50 net. Philadelphia and London: W. B. Saunders Company, 1916.

IT is a long time since any adequate monograph, devoted to the subject of gastric cancer has appeared, and in this period there have been many changes not only in diagnostic methods but also in beliefs concerning etiology and in the manner of treatment. The author's extensive experience in Ann Arbor, Rochester, and Chicago have furnished him with an abundant material from which he has produced an excellent work. Etiology, pathology, and symptomatology are all treated fully and satisfactorily. The chapter on the blood in gastric cancer we believe could be improved. The serum reactions are mentioned and described, but their value is not discussed. The fact that the blood picture may simulate that of pernicious anemia is not mentioned. The discussion of the relation of gastric ulcer to gastric cancer is the best in the book. The author shows its great importance, admits that it is impossible of absolute proof, and yet forces the reader to concede that there is no doubt a very intimate relationship between the two. He apparently has not much use for the Roentgen ray. Öchsner's chapter on the surgical treatment is an admirable one. The work is a production of the highest class and can be unreservedly recommended to all practitioners of medicine and surgery.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held December 28, 1915.

DR. GEORGE W. KOSMAK, IN THE CHAIR.

Premature Separation of Normally Situated Placenta Due to Shortening of the Cord.—Dr. LUCIUS A. WING reported this case. He said the patient was a primipara, 28 years of age, who at the time of her admission to the hospital gave a history of having had weak labor pains for about fifteen hours. For the past seven hours she had had bleeding from the vagina which became quite active. The attending physician had packed the vagina with iodoform gauze and had made a diagnosis of placenta previa. On admission to the hospital the patient's general condition was good. The uterus was very firm and remained more or less tonically contracted. On removal of the vaginal packing the cervix was still thick and barely admitted the tip of the finger. No placenta could be felt. Uterine contractions occurred every four or five minutes and were of moderate force and duration. The fetal head presented above the pelvic brim but did not come into the brim when the uterine contractions occurred; it moved laterally in the direction of the right iliac fossa. The patient had a justo-minor and moderately flattened pelvis, the true conjugate being 8.5 cm.; but as the child was small and the patient three or four weeks before term the somewhat diminished size of the pelvis was not sufficient to explain the failure of the head to engage. The condition could only be explained by some cord entanglement, with partial separation of the placenta. Abdominal cesarean section was decided upon as the quickest and most satisfactory method of dealing with the situation. At operation an oval placenta was found. The attachment of the cord was almost marginal at the lower border. The placenta measured 14 x 17 cm. and the cord was 43 cm. in length. Two coils of this cord were about the child's neck, and held the head close to the lower border of the placenta. The mother's post-partum course was very satisfactory.

Erythema Nodosum as Post-Partum Complication.—Dr. LUCIUS A. WING reported this case, which occurred in a primipara, 22 years of age, and pregnant seven and one-half to eight months. He said that twenty-two hours before admission to the hospital she had fallen heavily against the rim of the bath tub, striking her abdomen and left forearm. This was followed by abdominal discomfort, which continued to increase until, at the end of three or four hours, the patient was having severe abdominal pains, cramp-like exacerbations, and severe backache. About ten hours after the fall the patient began to bleed from the vagina, though not profusely. When brought to the hospital she was nearly exsanguinated and mildly delirious. Examination revealed a long cervix which barely admitted one finger and no placenta was felt. The uterus was tonically contracted. No fetal heart was heard. The small vagina and undilated cervix together with the desperate condition of the patient made it seem advisable to empty the uterus at once by laparotomy. The blood count on admission showed red cells 2,210,000, white cells 13,200, polymorphonuclears 80 per cent., and hemoglobin 33 per cent. When the uterus was exposed it was found firm and somewhat distended, and much deeper in color than normal, being a deep purplish red and showing numerous petechial areas. On incising the uterus the fetus was found in the region of the fundus and almost entirely separated. The dead fetus, membranes, placenta, and a great quantity of clotted blood, were quickly removed and the uterine incision sutured. The patient was discharged on the twenty-second day at her own request, though still quite anemic. Twenty days later she was again admitted to the hospital, complaining of weakness, headache, pains in the back and limbs, particularly in the large joints, slight sore throat, and slight cough. There was evidence of slight bronchitis and a mitral stenosis was present but showed no change since her former stay in the hospital, beyond the increased pulse rate, this being 110. Both arms and legs were dotted with a deep red nodular eruption, confined to the extensor surface. At the time of admission her blood count was as follows: red cells 4,070,000, white cells, 6,400, polymorphonuclears 72 per cent., and hemoglobin 60 per cent. The urine was highly

colored and showed an excess of indican. The patient continued to run a temperature for fourteen days, during which time the eruption gradually faded and its nodular character disappeared. There was some desquamation overlying each nodule. The blood culture showed a growth of streptococcus viridans. The patient was discharged on the twenty-second day, her temperature having been normal for a week.

Dr. HENRY DAWSON FURNISS said the case just reported was interesting to him because of the blood count following transfusion. There was at the Post-Graduate Hospital a woman who had bled profusely from a carcinoma of the cervix. Her blood count had fallen to 2,700,000 red cells and hemoglobin 45 per cent. After the transfusion of 480 c.c. of blood her blood count fell to 2,300,000 red cells and hemoglobin 40 per cent. The patient then began to improve during her stay in the hospital and the improvement had continued since. When a small amount of blood was transfused it seemed that one should be on the lookout for a reaction afterwards. It was better to infuse a greater amount in the first place. In this case hemolytic and agglutination tests were satisfactory and there was no evidence of hemolysis following the transfusion.

Spontaneous Rupture of a Pregnant Uterus Presenting Abdominal Symptoms of a Mild Degree.—Dr. T. H. CHERRY reported this case. He stated that the patient was thirty-five years of age, the mother of six children, and in her eighth month of pregnancy when she was admitted to the Harlem Hospital. The day before admission she began to have cramp-like pains in the lower abdomen, and a midwife told her she was in false labor. The pains continued with dyspnea on lying down. A physician was then called who confirmed the midwife's diagnosis. Although the patient's symptoms were referable more to the chest than abdomen, and although examinations of the heart and lungs disclosed no lesion, it was deemed advisable to terminate labor. A modified Ribes bag was inserted through the cervix. The following day as no labor pains had occurred, and the patient's condition remained unchanged, it was decided that the best way to deliver her was by cesarean section. Upon opening the abdomen and entering the peritoneum a moderate amount of blood was found free in the peritoneal cavity with the fetus and placenta among the intestines. These were delivered through the abdominal incision. The fetus was a dead anencephalic monster. The uterus was well contracted and showed a longitudinal tear on its anterior and lateral walls, extending from the junction of the fundus and lower segment near the midline to the vesico-uterine peritoneal fold, and laterally to the right broad ligament. Manipulation started fresh hemorrhage which made it advisable to remove the uterus supravaginally. The patient made an uneventful recovery and was discharged from the hospital on the sixteenth day. The uterine specimen was unfortunately mislaid so that it could not be determined whether any degenerative process was present in the uterine muscle. This case was of interest because, although the symptoms were entirely due to the conditions originating in the uterus, the local manifestations were slight and the cardiac symptoms were so marked that attention was directed principally to them.

Rupture of the Uterus Sustained During Version, Unrecognized Until Prolapse of the Intestines Forty-eight Hours Later.—Dr. T. H. CHERRY reported this case which occurred in a patient, thirty-six years of age, who had had four normal pregnancies and labors. Her present pregnancy had been normal. When she entered into labor her physician found a shoulder presentation with one arm protruding through the vagina, the uterus tonically contracted, and the cervix fully dilated. Under chloroform the physician performed a difficult internal podalic version with subsequent extraction of a dead child. A retained placenta was removed by manual extraction. The patient presented a normal appearance for the two following days when a cathartic was given. This was followed by a free movement of the bowels, at the termination of which she complained of abdominal cramps, nausea, and extreme weakness. Vaginal examination showed several loops of intestine prolapsed into the vagina. The patient was immediately sent to the Columbus Hospital, where an abdominal section was immediately done. On entering the peritoneal cavity with the patient in the Trendelenburg position a considerable length of small intestine was found lying free at the pelvic brim entirely detached from its mesentery. On following up this loop it was ascertained that the detachment of the mesentery from

the gut reached to the duodeno-jejunal junction, a distance of three feet. There were no signs of peritonitis or of free blood in peritoneal cavity. A rapid resection of three feet of the jejunum was made and a side to side anastomosis was done by the suture method. Examination of the uterus disclosed a longitudinal laceration in the lower segment on its posterior surface which extended to the cervix at its vaginal junction. This was sutured with interrupted chromic gut sutures. The patient left the operating room in fair condition. Later in the evening her temperature rose to 106°F., there was an increase in pulse rate, and she died a few hours later. In this case a complete rupture of the uterus had occurred during an operative delivery causing practically no shock or hemorrhage, and a period of forty-eight hours elapsed before prolapse of the intestine occurred. This was undoubtedly produced by the administration of the cathartic which produced active peristalsis, while at the same time the use of the voluntary muscles of evacuation increased the abdominal pressure causing the prolapse of the intestines through the uterine rupture. The uterus then contracting grasped the prolapsed intestines and held them in a fixed position.

Gas Bacillus Infection Following Futile Attempts at Induction of Labor.—Dr. T. H. CHERRY reported this case. He said the patient gave a history of having had one full term baby and two still births at term. At the time of admission to the hospital no fetal hearts could be heard and the mother stated that she had felt no fetal movements for two weeks, neither could the small parts of the fetus be felt. The patient was kept under observation for two weeks when it was decided to empty the uterus. The patient was prepared for this procedure by the most approved aseptic methods and a Ribes bag was introduced, after instrumental dilatation made necessary by the sclerosed condition of the cervix due to previous lacerations. Twenty-four hours later no labor pains had been produced and a larger bag was introduced, aseptic methods being carefully observed. During the next sixteen hours there were no labor pains and no softening or dilation of the cervix occurred. The patient then complained of nausea and chill, and an elevation of temperature was noted. After an attack of severe nausea and vomiting the patient suddenly expired, forty-eight hours after the introduction of the first bag. A partial autopsy revealed a dead fetus *in utero* and smears from the uterus showed typical bacilli *Aerogenes capsulatus*. While infection seldom followed the induction of labor where an aseptic technique was carried out, it was worth noting that virulent bacteria might be introduced into the uterus even if the technique was carried out in as aseptic a manner as they knew how. Dr. Cherry said that if he encountered such a condition again he would perform a vaginal cesarean section, as this procedure was the most rapid and certain mode of emptying the uterus after the third month of gestation.

Dr. JAMES A. HARRAR said that at the Lying-in Hospital when they had a case of ruptured uterus sent in they preferred to do a rapid hysterectomy rather than attempt to suture the rent in the uterus, especially when so extensive as the one described. They usually made no attempt to close the peritoneum over the opening in the vaginal vault. The women with ruptured uteri were admitted in desperate condition and it was noteworthy that those cases in which a hasty operation with drainage but with no attempt at the niceties was done recovered more frequently than those who, being in better shape, encouraged the operator to take pains in closing the peritoneum over the stumps of the tubes and amputated cervix. Dr. Harrar related a case somewhat similar to Dr. Cherry's second case, which had occurred during an attempt to produce an abortion. The woman was three or four months pregnant and had a retroverted uterus. The physician who attempted to produce the abortion tore through the uterus at the junction of the body with the isthmus and drew down a loop of the ileum. The loop of ileum was torn free from its mesentery? Nine inches of the ileum was resected with a lateral anastomosis. This patient made a smooth recovery.

Dr. GEORGE W. KOSMAK said he wished to speak with reference to the possibility of injury to the intestines without rupture of the uterus occurring during labor, and to relate an interesting case which he would report more in detail at a future time. This patient, a primipara, a few hours after normal labor suddenly went into shock, and fourteen hours later was admitted to the Lying-in Hospital with the belief that the uterus

might have been ruptured. The abdomen was slightly distended and there was more or less pain in the iliac fossa. There was no evidence of intraperitoneal hemorrhage. Upon opening the abdomen a considerable quantity of straw colored fluid was seen and there was complete gangrene of the sigmoid portion of the descending colon. The abdomen was simply closed with drainage and the patient died two hours later. At autopsy a complete gangrene of the sigmoid was found and there was no evidence of thrombosis formation indicative of obstruction to the blood supply, but the sigmoid was very movable. Examination showed no other lesions. The explanation seemed to be that the head, during the process of engagement, carried the movable gut with it and the pressure injury thus inflicted caused the gangrene. There was nothing in this instance that could have been done. The case showed conclusively that injury to the intestines even in normal labor was possible.

Backward Dislocation of the Lower Humeral Epiphysis as a Birth Injury.—Dr. EDWARD D. TRUESDELL gave a lantern slide demonstration which brought out a number of points of interest with reference to injuries of this nature. He said that in the new born child one or both arms might hang motionless; most commonly when this was the case a fracture of the clavicle or humerus was present, or an Erb's birth palsy might have occurred. During the first few days of life a syphilitic periostitis might cause a dangling arm, but a less common cause was a dislocation of the lower humeral epiphysis, a condition more often suspected than proven. The lower femoral epiphysis at birth quite regularly contained an ossification nucleus, as did the upper humeral epiphysis at times. Where this nucleus was present the x-ray picture would show the situation of the epiphysis, but without the nucleus the epiphysis being entirely cartilaginous could not be precisely located by the radiograph. When periosteum was stripped from bone in the new born, new bone formation took place beneath this periosteum very promptly and was visible in the radiograph at the eighth day after birth. This was noted quite regularly in cases of fracture of the humerus in the new born. By hyperextension of the forearm upon the arm in full term still born infants, backward dislocation of the lower humeral epiphysis was produced experimentally in one-half of all attempts made. These dislocations were dissected out, and it was found that the cartilaginous epiphysis was displaced backward, while it was still attached to the posterior portion of the periosteum of the shaft, which was stripped upward for a variable distance. In a case of backward dislocation of the lower femoral epiphysis studied at the Lying-in Hospital, the diagnosis was made by radiograph, the situation of the epiphysis being indicated by the contained nucleus of bone. Serial radiographs of this case extending over seven months were made. The dislocated epiphysis was not replaced. New bone formation began quite promptly beneath the periosteum, which was evidently stripped up following the epiphysis backward. Nature effected the repairs very satisfactorily during the seven months, constructing a new portion of femoral shaft to meet the displaced epiphysis and at the same time absorbing the superfluous bone in front. The present study was based on three cases in all of which version and breech extraction had been done. In each instance there had been extended arms causing great difficulty in delivery. In each infant there was a dangling arm. The first case was seen at the eighth day when a callous mass was felt just above the elbow joint and a diagnosis of supracondylar fracture made. The radiograph showed no fracture, but did show a deposit of new bone about the terminal portion of the humeral shaft. This was the only observation made in this case, the true nature of the injury not being fully realized. In the second case, the conditions of the arm being similar to the first, two radiographs were made. New bone was found around the lower portion of the shaft of the humerus, particularly evident in the lateral view; the deposit extended upward half the length of the shaft. In the third case it was thought that the humerus had been fractured, the diagnosis having been made before delivery was completed as the obstetrician felt some structure give away. There was distinct crepitus when the injured arm was examined. The radiograph showed no fracture, the bones appearing normal. At the eighth day new bone formation was shown in the radiograph, particularly in the lateral view, about the lower portion of the shaft of the humerus. Some thirty pictures were made of

this arm during the next three and one-half months. New bone formation was shown for nearly the entire length of the humeral shaft increasing in amount from above downward. At the same time there was a beveling off of the lower portion of the humeral shaft in front, a modified arrangement effected to meet the backward dislocation of the cartilaginous epiphysis, invisible in the x-ray. From the manner in which these injuries occurred, from the experimental evidence, from the radiographs of these three cases, and from analogy between these three cases and the case of dislocation of the lower femoral epiphysis, it would seem that backward dislocation of the lower humeral epiphysis did occur as a birth injury, and furthermore that this lesion was one definitely ascertainable in the radiograph made at or after the eighth day.

Post-Mortem Cesarean Section: A Report of Ten Cases.—Dr. JAMES A. HARRA presented this communication. He said that occasion might arise to handle the situation of a pregnant woman dying undelivered. She might or might not be in labor. The confusion accompanying the catastrophe to the mother might often cause the attendant to neglect the opportunity as well as the duty of rendering instant assistance to the unborn child. The operator might also be embarrassed by the necessity or the inability of obtaining consent for any operative maneuver upon the dead mother. Thus in many instances the baby's life was sacrificed when a prompt incision of the abdomen and uterus would rescue it without difficulty. The civil law in Rome dating from the time of Numa Pompilius decreed cesarean section in pregnant women dying undelivered. That post mortem delivery was recognized in ancient mythology was borne out by the reputed births of Bacchus and Aesculapius by this method. The Church also reproduced the injunctions of the Roman law. Unfortunately for many years and even at the present time post mortem delivery had resulted in surprisingly few living children. Attempts at post mortem extraction were sometimes made by version or forceps, preceded it might be by vaginal hysterectomy or manual dilatation. These procedures were generally doomed to failure, except in the case of death occurring toward the end of the second stage when a prompt low forceps or rapid extraction of a breech was the correct procedure. A certain repugnance among the laity to post mortem delivery of the dead woman was not unnatural, and to avoid later embarrassment it was always better to secure the consent of the husband or family if instantly at hand. If consent was not promptly to be had or if it was refused and the fetal heart was still going, it was not only permissible but imperative that the physician should do everything in his power to save the child. That the operation of post-mortem cesarean section was legal without consent had been shown by Bacon. He pointed out that the right of the husband to the custody and control of his wife's dead body did not go to the extent of preventing disposal of it as might be necessary to keep it from injuring another human being. The viable human fetus had the same right to live as had any other human being. This rule would require a post mortem delivery in every case when the fetus was of at least the twenty-eighth week of gestation and was known to be alive at the time of the mother's death. The legal status of a child born by post mortem cesarean section might at times prove to be of importance. The proposition of whether a child delivered after the death of the mother would share in the distribution of an insurance policy of the mother for the benefit of her children, living at the time of her death, was put up to the head of the legal department of one of New York's largest insurance companies. He gave it as his opinion that such a child would share in its mother's estate, and that the company would pay its share in the policy described without question. In 91,000 pregnancies at or near term at the Lying-in Hospital, 50 women had died undelivered. The great majority of these perished in less than an hour after their reception into the hospital, some dying while being admitted. In 19 instances the medical attendant considered it proper to take advantage of the opportunity of doing a post-mortem delivery. Seven times version was done, resulting in seven still births. Once a low forceps concluded the birth of a living child, the head being on the perineum when the mother died. Once a breech extraction was completed after the death of the mother with a living child. Ten times a cesarean section was performed and it was these cases which the writer discussed more particularly. In summarizing this series of cases he

stated that three babies were still born. It was probable that the death of all these children occurred before the death of the mother. Four babies were born with hearts feebly beating, but there was no attempt at respiration after prolonged efforts at resuscitation. One baby gave a few feeble gasps and died shortly after delivery. One baby, though badly asphyxiated at birth, left the hospital living and well, and one, crying spontaneously at delivery, was also discharged living and well. This showed what might be expected in a general way as to the success of post-mortem delivery by cesarean section taking the cases as they came. DeLee stated that a fetus would live from five to twenty minutes after the death of the mother, and that reported cases of longer periods were not authenticated. The length of time of survival depended upon the suddenness of the mother's death. The child lived longer if she died of apoplexy, accidental hemorrhage, eclampsia, or very acute infection, than if the agony was prolonged, as in tuberculosis, heart disease, etc. Since the mother used up the child's oxygen the latter usually died first. In the cases reported in this paper the longest interval between the death of the mother and the delivery of a living infant was seven minutes. One delivered after eight minutes gave a few feeble gasps and died shortly after birth. One delivered after an interval of twenty minutes had a feebly beating heart but never made any attempts at respiration. The obvious observation was that the success of the operation depended very much upon the promptness with which it was done. Unless one had positive proof that the baby was dead, when the mother succumbed it was justifiable to proceed at once to post mortem cesarean section. A point to be emphasized was the importance of persisting in prolonged efforts at artificial respiration as long as any intermittent contraction could be appreciated in the baby's heart by pressing the fingers up under the left costal margin. The children delivered in by post mortem cesarean section were almost invariably born in severe asphyxia and great patience was required in their resuscitation.

Mr. GEORGE A. WHITESIDE, Counsel for the Medical Society of the County of New York, said that the subject of cesarean section had received but little mention in either the reported cases or in the text-books of law, although it had been legally defined in Black's Law Dictionary as follows: "A cesarean operation is a surgical operation whereby the fetus, which can neither make its way into the world by the ordinary natural passage, nor be extracted by the attempts of art, whether the mother or fetus be yet alive, or whether either of them be dead, is, by a cautious and well timed operation, taken from the mother with a view to saving the lives of both or either of them." Where a post-mortem cesarean section was performed the situation was apparently anomalous, wherein the child was brought into the world after the mother's death and its property rights might, by reason of such fact, become seriously endangered if the ordinary principles of law were not in some wise adapted to this unusual condition. Both at Common Law and under the Statutes of our States, recognition had long been given to the rights of the posthumous child, this term being usually regarded as defining a child born after the death of its father and within the usual period of gestation. The Encyclopedia of Law and Procedure however, recognized that this early conception and definition of posthumous child should be extended to include likewise a child born after the death of the mother when cesarean section had been performed. For the purposes of property rights a child *en ventre de sa mere* was considered in *esse*; so that in law the time elapsed between the death of the father and the birth of a previously begotten child was completely annihilated. If this statute applied likewise to the posthumous child of the mother, then the property rights of such a child derived through intestate succession were in every wise similar to those of a child born prior to the mother's death. The statute referred to the intestate in the masculine gender, in the phrases "begotten before his death" and "in the lifetime of the intestate should he survive him." By the method of statutory construction "Words of the masculine gender included the feminine and the neuter, and may refer to a corporation or a Board or other body"; so that by this construction it would appear that a posthumous child born by post mortem cesarean section would have the same right of inheritance under the intestacy of its mother as though the death of the mother had occurred subsequent to the child's birth. A review of the Statute Law and of its

history and its construction in connection with the Descendant's Estate Law makes it plain that a child born as a result of post-mortem cesarean section, whose mother had hitherto made a will in which such a child was unprovided for and not mentioned, should receive the same portion of such parent's real and personal estate as would have been distributed to it if such parent had died intestate. So then as regarded the rights of a child born by post-mortem cesarean section, both under the intestacy of its mother and also where the previously made will of the mother did not mention or provide for such child, its rights were in no wise lost and were preserved as fully as those of a child normally born and not posthumous. Again, in the creation of estates in real property the position of the posthumous child was defined as follows: "When a future estate is limited to heirs of issue or children, posthumous children shall be entitled to take in the same manner as if living at the death of their parent and a future estate dependent upon the contingency of the death of any person without heirs, or issue, or children, shall be defeated by the birth of a posthumous child if such person is capable of taking by descent." By a section of the Code of Civil Procedure, an executor or administrator of a decedent who had left him surviving a husband, wife, or next of kin, might maintain an action to recover damages for a wrongful act, neglect, or default, by which the decedent's death was caused. Under this statute it would appear that if a woman about to give birth to a child, upon whom a surgeon was about to perform a cesarean section, were suddenly killed by the negligent act of another, and the surgeon thereafter delivered by post-mortem cesarean section a living child, the father thereof having died, an administrator could be appointed for that child and an action could be instituted for the death of the mother, and damages recovered for the death for the benefit of the child. If the mother's death were due to the negligence of the surgeon Mr. Whiteside said he saw no reason why a similar action could not be brought for the benefit of the child against the surgeon. As to the possible criminal responsibility of the surgeon performing post mortem a cesarean section or refusing to perform such operation, the Penal Law defined homicide as follows: "Homicide is the killing of one human being by the act, procurement, or omission of another." Where the cesarean section was performed before the mother's death, it was designed to preserve the life of both mother and child, so that in its proper performance there could be no criminal responsibility. Where, however, it should be performed by the surgeon and he neglected to do so, the life of both mother and child might be sacrificed. If either mother or child was killed by the omission of the surgeon to perform the operation, did it not seem clear that the definition of homicide was satisfied? If the surgeon's omission to perform the cesarean section was due to his performance of other lawful acts looking to the saving of the lives of the mother and child by lawful means, with ordinary caution, and without unlawful intent, it would seem that such homicide, under these conditions, might be considered excusable. If one assumed that such an omission was homicide it did not constitute murder in the first degree unless there was a premeditated and deliberate design to effect the death of the person killed; or murder in the second degree unless there was also a design to effect the death of another, without the element of deliberation and meditation. But if such an omission resulting in death, was without design to effect death but by culpable negligence, it would seem that such an offense might be considered as manslaughter in the second degree. This last analysis of criminal responsibility Mr. Whiteside said was purely speculative and not founded upon any precedent. The principle, however, was well founded on precedent and had found expression in cases in which safety devices of recent invention, readily available, but unheard of or unknown a half century ago, were omitted from use by those upon whom the responsibility for their use rested, and when a man's life was sacrificed through such failure or neglect the courts had considered such omission as constituting culpable negligence, and had held those responsible therefore upon a charge of manslaughter in the second degree. This was particularly true in the engineering field, but its application to surgery awaited the opportunity which a specific case might afford. Mr. Whiteside said that all these phases which he had considered might be elaborated at great length.

Dr. JOHN VAN DOREN YOUNG asked whether the physician or surgeon who performed a post-mortem

cesarean section performed an autopsy, and whether he was liable under the law forbidding the performance of an autopsy without the consent of the family of the deceased. The legal status of the baby born by post-mortem cesarean section had been very thoroughly cleared up but they had not been told whether the doctor might not be criminally liable who performed a post-mortem operation without the consent of the husband or relatives.

Dr. THOMPSON T. SWEENEY said that it seemed that the success of a post-mortem cesarean section depended upon the time that elapsed between the death of the mother and the extraction of the child, on the rapidity with which the operation was performed after the death of the mother. He felt that one would spend four or five minutes trying to resuscitate the mother and that personally he should hate to perform a cesarean section without doing this, and yet if the operation was to be successful it must be done rapidly.

Dr. J. A. HARRAR said that there was one point that he expected was of more interest to them as doctors than to Mr. Whiteside as a lawyer, and that was whether it was necessary to get the consent of the family before performing a post-mortem cesarean section, or whether the doctor had the right to go ahead and operate even if such permission was refused, viewing the question from the standpoint that in performing such a post-mortem cesarean section he was simply removing inert matter that was endangering the existence of a living human being. They would like to know what was the legal duty of the physician with reference to performing a post-mortem cesarean section where there was a possibility of getting a living child by this procedure. As to what had been said with reference to operating a few minutes after death, it seemed to him that one could usually make a safe decision, especially with a woman dying under observation, with a working diagnosis of the cause of her death. In such a case simple tests should enable one to assure the family that the mother was dead and that an attempt to save the life of the child was necessary.

Mr. WHITESIDE said that as to whether a surgeon should get the permission of the husband before performing a post-mortem cesarean section, this question could not be definitely answered until the Court of Appeals gave a decision. It seemed to him that when the physician was given charge of the expectant mother he was given charge of the lives of two human beings, mother and child, and he was thereby given implied authority to do all that science made possible to conserve the two lives committed to his care. If the mother died, his responsibility so far as her life was concerned was at an end and any cutting operation on her body was in the nature of an autopsy; but the surgeon still had the responsibility of doing all that science enabled him to do for the preservation of the life of the child, and this duty he owed by the implied agreement when he was put in charge of the case. It carried with it the authority to perform a post-mortem cesarean section without the consent of the husband, in his judgment. Of course this operation was in the nature of an autopsy and could not be performed without the consent of the husband or family, but this consent had been given when the life of the child was committed to the care of the physician when he took the case.

SECTION ON SURGERY.

Stated Meeting, Held January 7, 1916.

DR. JOHN DOUGLAS IN THE CHAIR.

Tuberculous Cervical Adenitis Treated by X-Ray.—Dr. A. F. HOLDING presented two cases.

CASE 1. This patient was eight years old. His trouble began in the summer of 1914 with a sore around the matrix of the index finger which was treated as an acute infection of the finger at two dispensaries. When the glands became enlarged at the bend of the elbow they were lanced. Dr. Holding said he was experimenting at this time on the action of various forms of electricity on infections and he went to various dispensaries asking for cases and this case was referred to him. When he first was on the case the glands of the arm, axilla, and the axillary portion of the chest were enlarged. Soon after the treatment was started an abscess formed over the right eye and, fearing that the infection was becoming general, cultures were taken which were reported as *Staphylococcus aureus* infection. A section taken from the finger and a gland

which was removed from the arm showed typical hyperplastic tuberculosis with some giant cells and tubercles. The diagnosis was then made of tuberculous adenitis based on the microscopical examination. The patient had received six Roentgen ray treatments and had gained very markedly in weight, strength, and general nutrition. He had now been perfectly well for over six months.

CASE II.—This patient was a woman, twenty years of age, with a negative family history. She had whooping cough at the age of one year which was followed by bronchial pneumonia, night sweats, cough, expectoration, loss in weight, and she had been confined to her bed for six months. After this time a small knuckle of bone was found in the back and she was treated for tuberculosis of the spine by Dr. Shaffer and Dr. Phelps. For six years she lived in a plaster-of-Paris cast which was followed by spinal braces. Her present illness began in 1910 when a hard lump formed in her left arm. This was lanced, after which there was a continuous discharge; similar lumps developed throughout the arm and axilla, as well as on both sides of the neck and front of the chest. In this condition the patient was referred from the New York Orthopedic Hospital to him, by Dr. Howard, with the diagnosis of tuberculous adenitis. Since April 15, 1914, she had received sixteen x-ray treatments and had been perfectly well of the adenitis and glandular involvement for over six months. The entire duration of her trouble was five years.

Fascia Transplants.—Dr. HAROLD NEUHOF presented a patient who had been under observation since nine months ago. There was a tracheal defect, and under local anesthesia a piece of the fascia lata was sutured in place with fine catgut. Leakage followed and it became necessary to drain the field. There was an extensive emphysema. Good results followed. The interesting features of this case were that the operation was done under local anesthesia and that the procedure employed was a very simple one.

He also presented a boy who had been under his observation for one year. He had a urethral defect and voided a small amount of urine through it, as well as through the normal opening. An operation was performed under general anesthesia; when the skin was peeled back a defect was found more than one-half the perimeter of the urethra in extent. By a very simple method the fascia lata was sutured over the defect and with perfect results.

Thyrectomy for Vagotonic Type of Basedow's Disease.—Dr. DEWITT STETTIN presented a young lady, 19 years of age. Her sister was a sufferer from Basedow's disease. Four years ago she first noticed a swelling in her neck, and two and a half years ago tremor, nervousness, slight exophthalmos, palpitation, and hyperidrosis became noticeable. She lost in weight and in spite of treatment her disease progressed. In July, 1914, the entire right lobe of the thyroid was resected, but she did not improve to any great extent and there was still no improvement. The remaining part of the left lobe continued to grow. Her chief complaints were tremor, extreme nervousness, hyperidrosis, swelling of the left side of the neck, and palpitation. She was admitted to the German Hospital on October 29, 1915. The patient showed the symptoms and physical signs of an advanced Basedow's disease. She weighed 119 pounds. She flushed easily and perspired profusely. She had a marked tremor. She was extremely nervous and restless. She was on the verge of a psychosis and she displayed choreiform movements of a pronounced degree. Her heart was enlarged and there was a moderate tachycardia, 120 to 130. There was a slight exophthalmos, but the various eye symptoms were not evident. There was a decided enlargement of the remaining portion of the left lobe of the thyroid. There was no presternal dullness. The x-ray examination showed only an enlargement of the heart. The blood count showed a leucopenia with a marked lymphocytosis, 5,300, with 50 per cent. lymphocytes. Her blood pressure was low, systolic 114, diastolic 68. She had no alimentary glycosuria. The adrenalin test was negative. The Loewi reaction was not present. There was a pronounced Aschner phenomenon (pulse before eyeball pressure, 110, after, 100). On injection of pilocarpine there was a most profound, even alarming reaction. The marked pilocarpine reaction, the decided Aschner phenomenon, the increased carbohydrate tolerance, even after adrenalin injection, the profuse hyperidrosis with the clammy extremities, the low blood pressure, the slight exophthalmos, and the moderate

tachycardia with subjective symptoms, all suggested that they were dealing with a case of Basedow's disease in which the vagotonic symptoms were at least pronounced, a case in which it might be presumed that the thymus had a preponderating influence. The patient's condition, in spite of three weeks' rest in bed and medical treatment, became worse and, although the case was not looked upon as the best operative risk, it was decided to remove part of the remaining thyroid tissue and at the same time to attempt a thymectomy as advised in this type of cases by Haberer, Klose, Garré, Halsted, and others. This was accordingly done on November 18, 1915, under general anesthesia. The remains of the left lobe of the thyroid were exposed through the old scar and the part resected. The exposure was very difficult owing to adhesions and cicatrix and there was considerable oozing. A second incision was then made perpendicular to the transverse one and this was extended downwards to below the suprasternal notch. The anterior mediastinum was exposed and the fat and glandular tissue lying between the sternum and trachea was removed. The total mass was not large, about the size of a pigeon's egg. The patient left the table in considerable shock and with a pulse of 168. From this shock she promptly recovered, and, although they expected a stormy post-operative course, she made a most uneventful recovery. There was no acute hyperthyroidism whatsoever; there was only a very slight rise of temperature the first two days and the pulse came down in two days to 100 where it remained. It was really striking that the patient who was in such an unsatisfactory condition before operation that they were reluctant to attack the case surgically, showed so little reaction after a rather severe operation. In fact it was much less than was shown by the average Basedow's case after the ligation of a single artery. This was quite in line with the well-known experience of von Haberer after the removal of even a small fragment of thymus. The microscopical examination of the tissue from the anterior mediastinum showed it to be an atrophic thymus imbedded in fat. Since the operation the patient had steadily improved. Her choreiform movements had gradually left her and she had gained fifteen pounds in weight. The pilocarpine test was repeated and 0.1 grain had as little effect as a dose of distilled water. On the other hand, the adrenalin test had become positive. Her heart action was still variable, the blood picture had not changed and the tremor, though better, was still present. Dr. Stettin said he realized that this case was not a clear-cut one, nor could it be considered as a cure as yet, although there had been certainly a decided improvement. He felt, however, that the observation was of sufficient interest to warrant the presentation.

Dr. JOHN ROGERS said that every case of Graves' disease was not entirely dependent upon some disease of the thymus, although he had several times thought the thymus to be at the bottom of the trouble. He reported briefly three cases. One was a woman, sixty years of age, who had been troubled greatly with cough. Thyroidectomy was done but without benefit. Dr. Rogers explored the region of the thymus and found a mass there as large as the thumb nail. This mass was removed, which was followed by a marked improvement of the cough, but little improvement in the diarrhea which she had had for some time. In the two other cases he made a careful exploration but could find absolutely nothing to account for the symptoms. He had seen one case that was operated upon four times; one lobe of the thyroid was first removed, then the other, and finally the isthmus. This patient then developed a severe psychosis and she was a very difficult case to handle. She had involuntary defecation and urination. She drifted into the hands of an x-ray specialist who applied the rays over the sternum and with perfect results. Dr. Rogers did not know how to make a satisfactory explanation of the result of this treatment. There was no doubt but that affections of the thymus would sometimes induce certain mental disturbances which were akin to psychoses. He reported another case of a child who had twice been operated upon. He took out a portion of the thyroid and tied off the thyroid arteries and today the patient was living practically on thymus. She could go about and attend to her ordinary household affairs. If the thymus was stopped, there appeared at once an enlargement of the thyroid with its accompanying disturbances. That the thymus in these cases was at fault could not be demonstrated. In many instances they

would look for the thymus and it could not be found in its proper situation; it would be found located somewhere else.

Subclavian Aneurysm; Return of Pulsation after Ligation of the First Portion.—Dr. H. A. HAUBOLD presented this patient. She was admitted to the Harlem Hospital March 10, 1915. A diagnosis of subclavian aneurysm was made and operation upon the same was performed by Dr. Haubold two days following. System anesthesia was begun with the Bennett intratracheal (Minewin and Rafsky) by Drs. Schaub and Lombard. Much difficulty was experienced in the introduction of the tracheal tube; after this had been inserted the anesthesia was excellent. The thorax was immobile throughout the operation. An incision five inches long was made, beginning about the middle of the right clavicle, curving upward and ending at the left sternoclavicular articulation. The platysma was divided and the sternocleidomastoid muscle was exposed and cut across about one and a half inches above the clavicle. The muscle was dissected upward and downward, giving an exposure of the carotid sheath, which was opened, and the right common carotid artery, the internal jugular vein, and the vagus nerve were dissected clean. The internal jugular vein was severed between two ligatures at the level of the incision of the sternocleidomastoid muscle. The lower portion of the cut jugular vein was dissected downward, thus exposing the right subclavian artery with the vagus nerve passing over it. A fine silk ligature on a carrier was passed about the subclavian artery from below upward, internal to the vagus nerve. A heavy, No. 20, double silk ligature was tied to the fine silk and carried around. Each of the heavy silk ligatures were tied tightly side by side with a double turn at the first part of the knot. The two ends of the ligature were then tied together, forming the second part of the knot. The bleeding vessels were ligated. The sternocleidomastoid muscle was sutured with a double mattress stitch. The skin and platysma were sutured with catgut lock stitch. A rubber drain was inserted in the external end of the incision. The patient made a rather slow but uneventful recovery, but there was a return in the pulsation in the aneurysm. The patient felt good and was very comfortable.

A Study of Postoperative Pneumonia in the Presbyterian Hospital during 1915.—Dr. ALLEN O. WHIPPLE presented this paper, in which he stated that the unusual number of postoperative pneumonias during the months of February and March of last year attracted the attention of the medical and surgical staffs of the hospital to this subject. As a result there was a more systematic study of the cases, both from the bacteriological and clinical standpoint, certain conclusions were reached, and a more comprehensive plan for the investigation of the etiology of the disease to be carried out during the coming year had been formulated. They had collected all the pneumonias that developed on the surgical side and found that these numbered 42 out of 1,902 cases, or 2.2 per cent. Whether all of these were to be considered postoperative pneumonias or not was a debatable question. A careful clinical study of the cases seemed to divide them into three groups: 1. The cases that developed within the first to the fourth day after operation in patients that were in good physical condition before the operation. Of this group there were 33, or 79 per cent. 2. The cases that came to the hospital with a pneumococcus infection in a part of the body other than the lungs. There were three such cases, or 7 per cent. 3. The cases that developed a pneumonia either as a terminal complication in the presence of other severe infections or in the feeble senile patients, or where the pneumonia appeared after the patients had recovered from operation and the pneumonia was contracted as in regular life. There were six of these cases, or 14 per cent. Of the 42 cases, 30 were males, 12 females; 37 were adults and five were children. After reviewing these cases more in detail the writer concluded: 1. That a fairly large percentage of the cases would have been overlooked had it not been for the systematic examination and radiographing of the patients that gave no definite physical signs of pneumonia, but in whom there was a rise in temperature and blood count or an increased respiration rate with more or less cough. In all such cases radiographs were taken, provided the condition of the patient did not forbid his being taken to the x-ray room in bed or on a stretcher. In at least eight of the cases the radiograph showed the shadow of a beginning consolidation before the physical signs ap-

peared, or where the signs became frank after the temperature had dropped and where the search for signs of a pneumonia would not have been made. These cases would have been considered sharp postoperative reactions. Contrary to the current belief, the majority of the x-rays showed a lobar pneumonia rather than a bronchopneumonia. 2. The prevailing type of pneumonia, considered clinically, had been very irregular in the combination of symptoms and signs. There was no syndrome such as was seen in the typical lobar pneumonia of the medical wards. An atypical onset with a rise of temperature without chill, absence of fastigium, and the fall of temperature by lysis, absence of rusty sputum, the presence, as a rule, of a slight cough, with a relatively slight increase in the respiration rate, in many cases very little toxemia, and in cases uncomplicated by a concurrent or primary infection or by shock or asthenia, a low mortality as compared with the medical cases of pneumonia during the same year, had been the clinical characteristics of the surgical cases of this series. 3. These atypical features of the postoperative pneumonias were explained in a measure by the bacteriological findings in the sputum and blood cultures of the cases. This phase of the study of surgical pneumonia, which had been neglected until this last year at the Presbyterian Hospital, offered the most promising results in establishing the predisposing as well as the exciting causes of the disease as it was encountered on the surgical side. Dr. Whipple referred to the grouping of the pneumococci as demonstrated by Dochez and Avery at the Rockefeller Institute and said that Groups I, II, and III of the parasitical pneumococci were met with in the pneumonias of the medical wards and caused the severe typical syndrome of symptoms. In virulence they were classed in the order of III, II, I. All three of these groups were parasitic in that they were not found in normal throats, or if present in a person not having the disease it was because that individual had been exposed to a patient and was termed a contact case. The smaller subdivision of the pneumococci or the saprophytic group had been named Group IV, and represented about 20 per cent. of the stains obtained from cases of lobar pneumonia, and this frequency seemed to be fairly constant from year to year. This saprophytic group was obtainable in culture from 70 per cent. of the throats of normal individuals who were not contact cases. In connection with these facts it was very significant to note that of the 22 cases of surgical pneumonias in which sputum cultures and mouse inoculations were made after the onset of the disease 77 per cent. gave positive cultures for the Group IV type of bacilli, 16 per cent. gave cultures for the parasitic varieties. These bacteriological findings agreed with the fact that the pneumonias were atypical clinically and that they were of relatively low mortality, and there were no associated complications. The two cases that cultured the Group I had the typical onset and seven-day course of the severe medical type of pneumonia; both of these patients were extremely prostrated and one died. 4. The occurrence of so many cases was due in a measure to the fact that they were diagnosed more frequently than in past years and to factors that caused a lowering of the resistance of the individual to the saprophytic Group IV pneumococcus which was normally in the throats of those coming into the surgical wards. Among other predisposing causes to the development of the disease were recent or concurrent cold, intercurrent infections with which many cases came to operation, lowering of the patient's resistance directly due to operative procedure, as hemorrhage, devitalization of tissues, especially in operations involving the upper respiratory tract, fasting, the recumbent position of the patient often for long periods before and after the operation, change to lighter clothing, and the lower temperature of hospital wards, and exposure during operation. The term ether pneumonia must be discarded and even postanesthesia pneumonia seemed to be a misnomer, considering the many predisposing factors that entered into the etiology of the disease. From the study of this series of cases, considered from the standpoint of the care of the patient, before, during, and after anesthesia, three recommendations might be offered to improve the prophylaxis against the disease: (1) Patients coming into a hospital with a history of recent cold or inflamed condition of the upper respiratory tract should not be operated upon until they were free from this predisposing cause. (2) A thorough revision of the admission routine for the ambulant cases, as regarded cloth-

ing and care from the time the patient had his admission bath until his admission to the operating room, and during, and immediately after the operation. (3) Ether should be served in small cans and any ether remaining in the can after an anesthesia should be sent to the laboratories or used in the preparation of catgut. Cultures of the sputum of every case should be taken during the twelve hours preceding the operation. When cultures showed the Group IV pneumococcus, a second culture should be taken twelve hours after the operation to determine how constant the presence of the pneumococcus was in the throat of the patient before and after the operation. If Group IV was found after the operation the two cultures should be compared for virulence to determine any increase in virulence following operation. If the patient developed a pneumonia, a culture of the sputum should be made to compare with the two preceding cultures. Blood culture of each case developing a pneumonia should be made as soon as the diagnosis was made. Radiographs should be taken in every doubtful case of postoperative rise in temperature. Comparisons should be made of the morbidity records of the medical pneumonias in this hospital and board of health records to determine whether the increased number of pneumonias in non-surgical cases was paralleled by an increase in surgical pneumonias.

Differential Diagnosis between Pneumonia and Acute Appendicitis Made by Roentgen Examination before Physical Signs of Pneumonia Obtained.—Dr. LEON THEODORE LEWALD read this paper, in which he stated that to avoid the possibility of operating upon an appendix which was not the seat of acute inflammation in a case of beginning lobar pneumonia the Roentgen ray might be used with considerable assurance of making a positive differential diagnosis, in cases in which all other diagnostic signs failed. Abdominal rigidity and tenderness over the region of the appendix might be present in certain cases of acute lobar pneumonia, the explanation of which was not evident. Temperature, pulse, respiration, and pneumocytosis might be exactly the same in both pneumonia and appendicitis. Typical signs of consolidation of the lung might not be obtainable during the first twenty-four, forty-eight, or even seventy-two hours after the onset of the illness, though indefinite signs suggestive of bronchitis might be present. If one followed the usual dictum that in cases of supposed acute appendicitis one should operate within the first twenty-four hours, he would occasionally find that he was operating upon a case of acute lobar pneumonia. In these doubtful cases the roentgenological examination frequently came as an aid. As an illustration of this Dr. LeWald cited the case of a child seven years of age, who was brought to him for roentgenological examination. The child had been ill with cough, slight nasal discharge, and slight fever for about five days; then two days before she had felt better and went outdoors. She came back with a chill and went to bed. Within a short time she began to vomit and complained of severe abdominal pain. There were no signs in the chest except bronchial râles which she had had for a week previous. The abdomen became distended and tender, more soon on the right side. The child's temperature was 104° F. Roentgenological examination revealed a distinct area of infiltration involving the central portion of the right lung. A stereoscopic examination confirmed the evidence of consolidation of the right lung. The evidence was presented to a surgeon, Dr. John Douglas, who suggested the possibility of there being a pneumococcus peritonitis. No operation was performed. The following day distinct physical signs of consolidation of the right lung were obtained. The high temperature and abdominal symptoms continued for three days. The temperature came down by crisis on the seventh day, following the initial chill. The patient went on to recovery, except for a slight otitis, which responded at once to paracentesis. A second case which Dr. LeWald reported likewise showed abdominal symptoms likely to be mistaken for those of appendicitis, but which proved to be due to a pneumonia involving the right lung and in which roentgenological examination showed complete consolidation over the upper third of the right lung at the height of the disease. There were certain difficulties which might be encountered in attempting this differential diagnosis, such as the presence of some old lesion in the lung casting a shadow, or the possible occurrence of a true appendicitis in conjunction with pneumonia.

Dr. RICHARD DERBY made a report on eleven cases of

postoperative pneumonia collected from the surgical service of St. Luke's Hospital, between January 1 and November 1 of last year. During this period there were 3,120 cases operated upon, showing a prevalence of this complication of .3 per cent. The anesthetics were given by the two women anesthetists of the hospital except in two cases anesthetized by the attending anesthetist to the hospital and one anesthetized by one of the house staff. Gas and ether was the anesthetic used in all but one case, where gas and oxygen were employed. The greatest amount of ether used in any one case was nine ounces; the average amount was 4.8 ounces. In all but one case the anesthetic was well taken, the color of the patient remained good, and the recovery to consciousness was not delayed. In the one case where the anesthetic was not well taken, the patient was cyanosed throughout the operation. The nature of the operation was an appendectomy in three cases. Two cases were simple mastoid operations, one was a radical mastoid operation, one an operation for repair of umbilical hernia, and one for repair of double indirect inguinal hernia. In the remainder of the cases the operation was an exploratory laparotomy, a hysterectomy, or a hemithyroidectomy. The longest anesthesia was one hour and forty-three minutes. The average length of anesthesia was fifty-five minutes. Three cases in this series died and no autopsy was made. No reference was made in the histories of these cases as to whether the examination of the sputum was made. No throat cultures were made. In one of the fatal cases, following a simple mastoid operation, a blood culture showed the pneumococcus after twenty-four hours' growth. An x-ray was taken in but a single case and the findings were questionable. There was no reference in the histories of any of the patients having a cold previous to the taking of an anesthetic. The physical signs of pneumonia were found in every case. In three of the eleven cases (27 per cent.), the signs found were those of bronchopneumonia; in the remaining eight cases the signs were those of a lobar pneumonia. The course in all but three cases was typical. It was very short, lasting but one or two days in one, and not exceeding six in any of the three cases. In these three cases the course and signs were so transitory that an embolic process was suggested as the origin of the pneumonia.

Dr. LEWIS S. BOOTH continued the discussion, giving a study of postoperative pneumonia that occurred at the Roosevelt Hospital. He said that during the year 1915 there were 2,612 operations at Roosevelt Hospital with 23 postoperative pneumonias, approximately 0.9 per cent. This did not include the operations under the Courtesy Staff, the records of which were not filed. Twenty of their pneumonias were lobar, and the other three involved limited areas. This would seem to indicate that exposure was the important factor in causing the majority of pneumonias, and that aspiration was responsible for only three. At Roosevelt they had no recovery room and every patient on the two general surgical divisions had to pass through the main corridor of the hospital before reaching the wards. In the winter and early spring months, when 15 of their pneumonias occurred, this corridor was often cold and draughty, and in extremely cold weather it had been found almost impossible to heat properly their two main surgical wards, which were unusually large, and which, opening along one side either onto a balcony or onto an open court, and, diagonally opposite, directly into the main corridor, were necessarily draughty. On the other hand, on the gynecological division, where, out of 501 operations, there were only two postoperative pneumonias, both of which were of the bronchopneumonic type, the patients did not have to pass through a corridor as the operating room directly adjoined the ward, which was itself small and more easily heated. Thus the fact that there had been no lobar pneumonias on that division would at least suggest that there was a certain amount of exposure while patients were passing through the main corridor and while they were recovering in a cold ward. Of their 23 pneumonias, 16 followed abdominal operations, which indicated that operative trauma was an important factor in lowering a patient's resistance to infection. Five followed operations on the stomach where the procedure was long and severe, and the patients were of the weaker type. Three followed removal of the gall-bladder, four followed operations for acute appendicitis with local or diffuse peritonitis, two followed abdominal explorations with removal of the appendix, one followed an abdominal hysterectomy, and one fol-

lowed an operation for tuberculosis of the pelvic organs. Of the remaining seven there were three following herniotomy, two after operation for harelip, one following incision and drainage of a periurethral abscess, and one following amputation of the leg for arteriosclerotic gangrene. During the first four months of the year, when fifteen of their pneumonias occurred, there were 41 pneumonias in the medical wards, 21 of which gave positive blood cultures. The infection was obviously running high throughout the city at that time, suggesting the possibility that in a certain number of cases, pneumonia might have developed even without operation. The ages of their patients varied from two to seventy years. In all but three cases, the physical signs of the lungs were normal before operation. One case showed an old healed apical tuberculosis, and two cases presented emphysema. Three patients were operated upon when a known infection was present in the respiratory tract. Ether was used in every case, but in one case only to supplement gas and oxygen. In all but three cases induction was accomplished with nitrous oxide gas. In five cases the induction was stormy with a moderate degree of cyanosis produced. In three cases there was excessive mucus present. The closed rebreathing method with the Bennett inhaler was used in 14 cases; the intratracheal method was used in three cases, all of which were long and severe operations on the stomach; the intrapharyngeal method in three; drop ether in two, and gas and oxygen supplemented by ether in one case. The anesthetics were all managed by the internes or by the paid anesthetist of the division. Postoperative vomiting occurred in all but two cases. In 11 cases the pneumonia appeared on the first day; in five on the second; in four on the third; in one case on the fourth, and in two on the fifth. The left lower lobe was involved in nine cases; the right lower lobe in five; both lower lobes in five; the entire right lung in one, and a limited area in three. In 12 cases the leucocytes were 18,000, or over. In four cases they were within the limits of normal. In the remaining seven cases a leucocyte count was not obtained. The temperature in no case fell by crisis. In three cases it fell by rapid lysis, and in the other cases, in which recovery was prompt, the temperature shaded off to normal in from five to seven days. In one case the temperature never rose above 100.4°. Blood cultures were taken in nine cases, with no positive results. The sputum was cultured in seven cases and no growth was obtained in any case. The diagnosis of pneumonia was verified by x-ray in three cases. They had just begun to make use of the x-ray for the diagnosis of postoperative pneumonias that did not present physical signs. Death occurred in seven out of the 23 cases, a mortality of about 30 per cent. In 12 of the 16 who survived the pneumonia recovery was complete. One case still had signs of consolidation but no temperature when discharged three weeks later; a second case presented râles at both bases two months after operation, and two cases were believed to have tuberculosis.

A Review of the Postoperative Cases of Pneumonia in the Second Surgical Service of the New York Hospital.—Dr. FREDERICK W. BANCROFT said that during the year 1915 there had been 15 cases of pneumonia in 1,413 operations, or 1.06 per cent. Of these cases of pneumonia seven had died, or 46.6 per cent., giving a total mortality of 0.5 per cent. A brief history of each of these cases and of the operation performed showed that of the seven fatal cases three deaths followed general peritonitis; one of these patients died at the end of the third day, another on the twenty-fourth day of pneumonia secondary to pulmonary embolism, and the third died of pneumonia secondary to suppurative pleurisy, due to subphrenic abscess. The other four deaths were due respectively to typhoid appendicitis, strangulated inguinal hernia, pelvic inflammatory disease, and cholecystitis, and should have been avoided. The diagnosis of the eight cases that recovered was chronic appendicitis three cases, ventral hernia, gastrotomy for carcinoma of the esophagus, inguinal hernia and hypertrophied tonsils, inguinal hernia, and cholelithiasis, each one case. Two of these cases were lobar pneumonias and six bronchial pneumonias. The onset occurred on the first day in three cases, and in one case each on the second, third, fourth, fifth and eighth days. All persisted from four to eight days and subsided by lysis. The x-ray taken in two cases showed signs like those of tuberculosis. The age of the youngest of this series was four years and the eldest 62. Everyone of the 15 operations was a lapa-

rotomy. The shortest operation lasted 15 minutes and the longest 60 minutes, the average time being 36 minutes. The time of the year did not seem to be a factor since three cases occurred in March and three in August, and one each in the other months. Three of the fatalities were in cases of severe peritonitis and the pneumonias might have been of the terminal type. The anesthesia in 11 of the fatal cases was gas and ether (Bennett inhaler, followed by the drop method), ethyl chloride and ether in two cases, gas and ether followed by chloroform in one case, local novocaine followed by gas and oxygen in one case. The bacteriology of these cases was not studied. The study of the bacteriology in Dr. Whipple's paper was most instructive and would tend to clear up the disputed question of whether the postanesthetic bronchopneumonias were true bronchopneumonias or multiple infarcts. The two cases in his series in which x-rays were taken and the signs were suspicious of tuberculosis later cleared up and it seemed probable that the shadows seen were multiple infarcts rather than bronchopneumonia. If the same organism found in the mouth was later identified as the cause of pulmonary infection it would suggest that the lesion was a bronchopneumonia. They had x-rayed their patients who had unexplained temperatures, provided they were in condition to move, but they had not considered it advisable to x-ray patients with positive physical signs. One of the greatest factors in the etiology of postoperative pneumonias was the operative nightgown. Many of the patients entering a hospital were accustomed to sleep in heavy woolen or flannel underwear; after entering the hospital they were forced to wear light muslin gowns open up the back. Often when the patient was on the operating table there was only a couple of layers of cotton between the metal operating table and the patient's unprotected back. Hospitals should provide undershirts of different weights so that the patient used to heavy weights might be properly protected until he was well out of the influence of the anesthetic.

PHILADELPHIA NEUROLOGICAL SOCIETY.

At a stated meeting held February 25, Drs. S. D. INGHAM and W. E. ROBERTSON exhibited a patient from whom a spinal tumor had been removed eleven months previously. The case occurred in a young woman who presented progressive weakness and impairment of sensibility in the lower extremities, with loss of knee-jerks and of control of the sphincters. Operation disclosed a cholesteatoma 5½ in. long, in the lower dorsal and upper lumbar regions, within the dura, removal of which was followed by almost complete recovery.

Dr. P. DE LONG exhibited "A Case of Tabes Dorsalis Associated with Paralysis Agitans." The patient was an elderly man who had presented symptoms of tabes for a number of years, when there developed passive tremor of the fingers, with fixed countenance and other stigmata of paralysis agitans. The association was looked upon as accidental and rare.

Dr. ALFRED GORDON exhibited "A Case Presenting Cerebello-cerebellar Symptoms." The patient was a young man who learned to walk and to speak late and who from early life was ataxic in walking and standing. As time went on the disorder of motion grew less, while speech became deliberate and precise, and evidences of mental deficiency appeared.

Dr. T. H. WEISENBURG exhibited "A Case with Unusual Spinal Cord Symptoms." The patient was a man who had lost motor power and sensibility in the lower extremities, but with Babinski response only on heavy stroking on the inner portion of the sole of the foot, together with firm contraction of the upper abdominal muscles on attempts to assume the sitting posture. Heavy stroking over the anterior tibial group of muscles induced dorsal flexion of the foot, while similar stroking over the peroneal muscles brought about rotation of the foot outward.

Dr. H. MAXWELL LANGDON exhibited "Another Case of Nontraumatic Isolated Cervical Sympathetic Paralysis." The patient was a middle-aged woman in whom the disorder had existed as an isolated condition for a good many years. There was a negative response to the Wassermann test. The upper eyelid on the affected side drooped, the palpebral fissure was correspondingly narrower and the pupil was smaller and acted less well on mydriatic stimulation than its fellow of the opposite side.

Dr. H. Clark reported "A Case of Tic of the Abdominal Muscles of Eighteen Years' Duration, with Necropsy." Some years following an injury of a remote part of the body by a heavy weight, the patient developed a spasmodic tic of the abdominal muscles, which persisted for many years. After death no lesion was found in the nervous system.

Dr. C. M. BYRNES reported "A Case of Bilateral Fifth-Nerve Paralysis." The patient was a man who had had the initial lesion of syphilis and was treated accordingly. While under observation loss of sensibility on both sides of the face gradually developed, together with loss of the sense of taste on the anterior portion of the tongue and dropping of the lower jaw. Under treatment marked improvement in the condition took place.

Dr. G. M. DORRANCE presented a communication entitled "Tic Douloureux." He discussed comprehensively the historical aspects of the disease, its etiology, pathology and treatment, devoting himself especially to a consideration of the therapeutic employment of injections of alcohol into the branches of the nerve or into the Gasserian ganglion. He described a technique developed as a result of extended observations upon the cadaver, supplemented by clinical experience.

Drs. J. H. W. RHEIN and WM. R. ADAMS exhibited "A Brain with a Tumor of the Dura, Showing Some Unusual Symptoms." The patient was found unconscious, with symptoms of hemiplegia and convulsive movements. Death resulted in the course of a few hours and post-mortem examination disclosed a tumor of the dura imbedded in the cortex of the paracentral region.

Progress of Medical Science.

STATE BOARD EXAMINATION QUESTIONS.

LOUISIANA STATE BOARD OF MEDICAL EXAMINERS.

December 2, 3, 4, 1915.

(Concluded from page 500.)

OBSTETRICS.

1. Name and describe the signs of pregnancy as determined by touch.
2. State the diagnosis and treatment of an inevitable abortion.
3. Diagnose by abdominal palpation and vaginal touch an R. O. P. presentation.
4. (a) What is the second stage of labor? (b) What conditions may cause delay in this stage? (c) How should such conditions be managed?
5. A primipara at the fourth month of pregnancy presents evidences of albuminuria, with no uremic manifestations; what treatment is indicated?
6. Should delivery become imperative, the head being only partially engaged, and the cervix partially dilated, how is delivery best effected?
7. (a) What is prolapse of the funis? (b) What the dangers? (c) Management?
8. (a) What conditions would necessitate artificial feeding? (b) Describe the proper modification of cow's milk for the newly born.
9. (a) What drugs are of use in labor? (b) State their indications and contraindications.
10. (a) State the maternal and fetal indications for the use of forceps. (b) What are the prerequisites necessary for their safe application?

GYNECOLOGY.

1. Mention the changes of cervix uteri which may be felt on vaginal examination.
2. Give differential diagnosis of syphilitic, tuberculous, and malignant ulcer appearing about the external genitals.
3. Give the principal points of diagnostic importance in connection with an abdominal examination.
4. A patient presenting herself for examination with a mass in right lower abdomen—what might it be?
5. Give special symptoms pointing to tubal pregnancy.
6. Of what use is the uterine sound?
7. What symptoms may follow retroversion of the uterus?
8. Name the causes of dysmenorrhea.

9. Why is gonorrhea in women a grave disease?
10. What is a urethral caruncle, and its treatment?

SURGERY.

1. Describe briefly the technique you would employ for a punctured wound of the foot caused by a pitchfork.
2. Give symptoms and treatment of acute catarrhal otitis media.
3. Differentiate between trachoma and conjunctivitis.
4. What is a carbuncle? How would you treat one?
5. Differentiate between typhoid fever and appendicitis.
6. What arteries need ligating in an amputation at the middle third of the leg?
7. What part of the vertebræ is usually affected in Pott's disease. Describe the pathological changes that take place.
8. Give diagnosis and treatment of acute osteomyelitis.
9. Name some of the bacteria of suppuration. Which ones are the most virulent?
10. Make a differential diagnosis between coma due to (a) injury, (b) apoplexy, (c) opium poisoning, (d) acute alcoholism.

PHYSICAL DIAGNOSIS.

1. Name the various abnormal respiratory sounds (râles), and indicate the physical conditions giving rise to each.
2. Differentiate pulmonary hepatization and pleurisy with effusion.
3. Differentiate impacted stone in the right ureter from other similar conditions.
4. What are the physical signs of pyloric stenosis?
5. What are the early symptoms and physical signs in pulmonary tuberculosis?

HYGIENE.

1. Name and describe briefly the methods of purification of public water supply.
2. (a) What is natural immunity? (b) Acquired immunity? Explain each.
3. Describe the disinfection of a room occupied by a careless consumptive.
4. State briefly the sanitary supervision necessary for the production of pure milk.
5. How are mortality rates calculated?

ANSWERS.

OBSTETRICS.

1. *Signs of pregnancy as determined by touch:*
(a) *Ballotement* is the passive movement of the fetus *in utero*, obtained by tapping the lower segment of the uterus with the index finger.
(b) *Hegar's sign* consists in a thinning and softening of a segment of the body of the uterus immediately above its cervix.
(c) *Braxton Hicks' sign* consists of intermittent contractions of the uterus at about the fourth month of pregnancy.
(d) *Rasch's sign* is fluctuation felt when the hand is applied to the cervix of the uterus in early pregnancy, due to the presence of liquor amnii.
(e) Active movements of the fetus, which can be felt by the physician's hand placed over the abdomen of the mother.
2. **INEVITABLE ABORTION.** (a) *Diagnosis:* Hemorrhage profuse and continuous, clotted and dark colored; pain cramp-like and severe; cervical canal dilated; uterus soft and enlarged, and the angle between the upper and lower uterine segments is effaced; the discharge consists of dark blood, clots, and portions of ovum; signs of pregnancy present, except amenorrhea.
(b) *Management:* "Two methods of treatment have been advised for these cases. The first is the *expectant plan*. Place the patient in bed, and if the bleeding is profuse, insert a tampon of iodoform gauze (one yard) well up against the cervix. If this fails to control the hemorrhage, reinforce it by another yard or two of gauze and a perineal pad and binder. Small doses ($3\frac{1}{2}$) of the fluidextract of ergot should now be given every two or three hours. At the end of from eight to twelve hours remove the tampon, when the ovum may be found extruded from the cervix; if not, a vaginal douche of mercuric chloride (1:4000) must be given, and another tampon introduced. If, upon the

removal of this second tampon at the end of ten or twelve hours, the ovum is not discharged, then more vigorous methods to secure its expulsion must be adopted. *Active plan:* The physician's hands and instruments are sterilized; the patient is etherized and placed on an appropriate table; the genitalia are thoroughly cleansed and a vaginal douche of mercuric chloride (1:4000) is given; the anterior lip of the cervix is brought down to the vulvar orifice; the cervix is dilated if necessary; the placental forceps is introduced into the uterus, and as much as possible of the ovum is removed; the uterus is thoroughly curetted, and an intrauterine douche of sterile water is given. A light tampon of iodoform gauze is placed in the vagina; the patient is then returned to bed. A strip of gauze may be placed in the uterus in cases of sharp retroflexion, to secure free drainage, and occasionally an intrauterine tampon will be necessary when the uterus refuses to contract and hemorrhage persists after the use of the curette."—(*Pocket Cyclo-pedia.*)

3. In R. O. P. positions, abdominal palpation shows that the back of the fetus lies to the right side and posteriorly, and that the extremities are above and to the left side and anteriorly. Vaginal examination shows that the occiput is depressed and points to the right sacroiliac synchondrosis; the smaller fontanel is also posterior and points to the right sacroiliac synchondrosis. The sagittal suture is directed from the small fontanel forward and to the left in the line of the right oblique diameter of the pelvis; the shoulders are in a line at right angles to this, in the left oblique diameter. Sometimes the anterior fontanel may be felt high up anteriorly.

4. The second stage of labor extends from the time that the os is fully dilated until the child is expelled from the uterus.

DELAYED LABOR. *Causes:* Obstruction, uterine inertia, uterine exhaustion. *Management:* The case should be treated early; causes should be removed when possible; a warm vaginal douche, and the administration of morphine, chloral, or quinine have been recommended; delivery by forceps may be necessary.

5. *Albuminuria with no uremic manifestations:* "The urine should be examined every month in the first six months of every pregnancy, no matter how normal it may seem, and every fortnight in the last three months. If albumin is present, the amount should be estimated in an Esbach tube, and the urea in a Doremus ureometer. The total quantity of urine per diem should also be ascertained. The principles of treatment are to relieve the kidneys by free elimination by the bowels and skin, and by diminishing the nitrogenous part of the dietary; and at the same time to prevent any further interference with the renal functions by guarding against cold. In mild cases where the albuminuria is the sole symptom, the patient should be warned to rest and guard against cold. The diet should be restricted to milk food, with bread and butter, and a little fish or chicken once a day, and the bowels should be made to act freely once every day. (Johnstone's *Textbook of Midwifery.*)

6. If the internal os is persistent, dilating bags may be tried; if these are not at hand, or not effective rapidly enough, cesarean section offers the safest method of delivery, though it usually entails some delay for preparations unless the likelihood has been anticipated. If the internal os is obliterated, manual dilatation is indicated, following this by forceps if the head engages, or by version if the head does not engage; or dilating bags may be used, followed by forceps or version; or the cervix may be incised, and the child delivered by forceps or version. If the patient is a primipara, forceps should be favored if possible on account of the better prognosis for the child and the lesser liability to serious traumatism of the mother's soft parts.

7. *Prolapse of the funis* is the condition in which the umbilical cord hangs down alongside of or in front of the presenting part of the fetus. *Danger:* Compression causes death of the fetus. *Treatment of prolapsed funis* consists in: (1) Not rupturing the membranes prematurely unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually or with some form of repositor; (4) speedy delivery, by forceps or podalic version.

8. *Artificial feeding is indicated:* If the mother dies; if there is absence of breast milk, eclampsia, tuber-

culosis, septic infection, severe hemorrhage, or chorea on the part of the mother; and in case of persistent loss of weight of the child.

Proper modification of cow's milk includes dilution, and the addition of cream and sugar of milk.

For a newborn infant, take the top 9 ounces from a quart of good milk, of this use 2½ ounces; to this 2½ ounces add one ounce of milk sugar and 17½ ounces of boiled water. This will give 20 ounces. The infant should receive about half an ounce every two hours for the first day, and about one ounce every two hours for the next six days. During the night the infant should be fed twice. This mixture is only suitable for the first week.

9. *DRUGS USED IN LABOR.* Bichloride of mercury, lysol, phenol, creolin, etc., are indicated as antiseptics for the vulva, and hands of physician and nurse. Boric acid and silver nitrate, are indicated for use in the infant's eyes, to prevent ophthalmia. Quinine, and strychnine are indicated in primary and secondary uterine inertia, but are contraindicated in eclampsia. Morphine is indicated early in labor in case of weak and inefficient pains and rigid os; if given later there is danger of fetal asphyxia. Chloral is indicated for the same conditions as quinine; strychnine and morphine. Veratrum viride is indicated in eclampsia and vascular hypertension; it is contraindicated in cases with slow and soft pulse. Chloroform and ether are indicated in the latter part of the second stage of labor to alleviate the suffering, and also in all obstetrical operations; chloroform is contraindicated in cases of very rapid fetal heart, and where the mother has cardiac disease; ether is contraindicated in cases of bronchiectasis, tuberculosis and eclampsia. Ergot is indicated in postpartum hemorrhage; it is given during the third stage to ensure good contractions of the uterus; it should not be given before the third stage of labor. Pituitrin is given for postpartum hemorrhage, secondary inertia, and induction of premature labor; it is contraindicated if the os is undilated, and must be used cautiously if the soft parts are not prepared for immediate delivery.

10. *Indications for the use of forceps* are: (1) *Forces at fault:* Inertia uteri in the presence of conditions likely to jeopardize the interests of mother or child. (a) Impending exhaustion; (b) arrest of head, from feeble pains. (2) *Passages at fault:* Moderate narrowing, 3¼ to 3½ inches, true conjugate; moderate obstruction in the soft parts. (3) *Passenger at fault:* A. Dystocia due to (a) occipito-posterior, (b) mento-anterior face, (c) breech arrested in cavity. B. Evidence of fetal exhaustion (pulse above 160 or below 100 per minute). (4) *Accidental complications:* Hemorrhage; prolapsed funis; eclampsia. All acute or chronic diseases or complications in which immediate delivery is required in the interest of mother or child, or both (Jewett). *Conditions necessary for the use of forceps* are: (1) The rectum and bladder must be empty; (2) the os uteri must be fully dilated; (3) the membranes must be ruptured; (4) the pelvis must be of sufficient size.

GYNECOLOGY.

1. *Vaginal examination* may show, with regard to the cervix, changes in position, shape, size, consistence, together with the presence or absence of erosions and lacerations.

2. "In syphilis the inguinal glands are involved, there is a single area of ulceration, and specific treatment gives positive results. In tuberculosis, on the other hand, the inguinal glands are seldom involved, the ulceration is multiple, and the results of specific treatment are negative.

TUBERCULOSIS.	CARCINOMA.
Very slow in development.	Not so slow.
Several nodules.	Single nodule.
Ulceration superficial.	Usually deep.
Margins of ulcer not everted.	Everted and undermined.
Margins of ulcer slightly infiltrated.	Marked infiltration.
Surface covered with bright red granulations.	Surface fungoid in appearance.
Tendency to repair ending with cicatrices.	No formation of cicatrices.
Rarely affects general health.	Cachexia.

(Ashton's *Gynecology.*)

3. The principal points of diagnostic importance in abdominal examinations are: Inspection, palpation, percussion, mensuration, and auscultation. By inspection, we can note the contour of the abdomen (hernia, ascites, tumors, pregnancy), movements of the abdominal walls (fetal movements), and the appearance of the skin (pigmentations, edema, lineæ albicantes, dilated veins). By palpation, we can note the presence of a tumor, the situation and origin of a tumor, the shape and mobility of a tumor, the consistency of a tumor, crepitation (peritonitis, adhesions), and local tenderness (peritonitis). By percussion, we note the presence of a tumor (solid tumor, ascites, tympanites), situation and origin and shape of a tumor. By mensuration, we can note the origin and nature of an enlargement. By auscultation we can note fetal heart sounds, sounds of placental circulation, vascular murmurs in uterine tumors and aneurysms, friction sounds in peritonitis, and movement of gas in the intestines. (From Ash-ton's *Gynecology*).

4. A mass in the right lower abdomen may be: Appendicitis, fecal impaction, intussusception, floating kidney, pyosalpinx, ovarian tumor or abscess or cyst, hematoma or hematocele, inguinal hernia, fibroid tumor.

5. Symptoms of tubal pregnancy are the signs of early pregnancy, hypogastric or inguinal pains, probable history of a previous sterility, probable expulsion of decidual membrane or shreds, softening of the cervix, slight enlargement of the uterus, presence of a distended tube, contractions of the wall of the gestation sac; if rupture occurs, there will be sudden, excruciating pains over the lower abdomen and on the affected side, shock, collapse, and symptoms of internal hemorrhage.

6. The uses of the uterine sound are: (1) to demonstrate the mobility of the uterus; (2) to show the size of the uterus; (3) to show the presence of intrauterine growths; (4) to indicate deviations in the cervical canal; and (5) as an aid in the diagnosis of uterine displacements.

7. The following symptoms may follow retroversion of the uterus: Backache, bearing-down pains, a feeling of pressure in the pelvis, constipation, hemorrhoids, frequent or painful urination, leucorrhea, menstrual disturbances, as dysmenorrhea or menorrhagia, sterility; there may also be general symptoms, as headache, indigestion, nausea, anorexia, neurasthenia, and general malaise.

8. Causes of dysmenorrhea: Pelvic congestion, pelvic inflammation, malnutrition, overwork, lack of development, neuralgia, stenosis or obstruction of the cervix, prolapse or displacement of the uterus.

9. Gonorrhea in women is so serious on account of the possible results: Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands. It often leads to chronic invalidism, and may be the cause of death.

10. Urethral caruncle is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

SURGERY.

1. In punctured wound of the foot, made by a pitchfork: First of all, take a smear and a culture from the wound, and examine for tetanus bacilli; if these are found tetanus antitoxin should be administered in doses of 10 cc. daily for a fortnight. The wound is then to be enlarged by incision, disinfected, and drained; foreign matter must be removed; injured vessels, nerves, or tendons must be treated separately.

2. "Acute catarrhal otitis media is frequently caused by acute coryza and the infectious fevers. There is a painless obstructed sensation in one or both ears, impairment of hearing, and tinnitus. The inflammation causes closure of the Eustachian tube. Inflation and aspiration of the middle ear and syringing and douching the nares and nasopharynx must be avoided. A moderate spray of Dobell's solution may be used. If pain is present, dry heat, in the form of hot-water bottle, hot stone wrapped in flannel, etc., may be applied. A few drops (100), warmed, of a carbolic acid solution (1:40), or one of formalin (1:2000), may be instilled into the ear.

3. "Chronic follicular conjunctivitis and trachoma

sometimes resemble each other. The former occurs in youth. The granulations are small, round, in rows, occurring especially on the nasal half of the conjunctiva of the lower lid and edge and extremities of the cartilage of the upper lid. The disease is amenable to treatment and the granulations disappear without leaving a trace. Trachoma, on the contrary, is a progressive disease, lasting for many years. The granulations are, as a rule, larger, less prominent, more uniformly distributed, and at last disappear, leaving cicatrices."

4. A carbuncle is a localized inflammation of the subcutaneous tissue, which goes on to sloughing, and is of a more extensive character than a boil. Staphylococci are the common exciting cause, while the predisposing causes are lowered vitality from diabetes, albuminuria, or after infective fevers. Inoculation is by autoinfection or directly from the surface. The disease begins as an infiltration of a patch of subcutaneous tissue, which is hard, painful, and tender, and the skin over it is red and hot. The infiltration may extend till it is the size of a dinner-plate, and the inflammation ends in sloughing and suppuration, not only of the subcutaneous tissues, but of small areas of the skin over it, so that openings develop in the skin, and allow of the exit of pus and sloughs. The openings extend, the sloughs separate, and the wound heals by granulation. The back is a common situation. Sometimes the face is affected, and there is then a danger of thrombosis extending to the cavernous sinus and producing pyemia. Treatment is very satisfactory if properly carried out. An anesthetic should be given, the slough thoroughly scraped away, the surface left treated with pure carbolic acid and dressed with antiseptic gauze. The patient should be fed on eggs, milk, cream, meat juice, and brandy. Codeine is necessary in diabetes, —(Aids to Surgery.)

5. Typhoid fever and appendicitis: In appendicitis, the pain and rigidity are more marked than they are in typhoid; in typhoid the pulse is slower than in appendicitis; there is a leucocytosis in appendicitis, and a leucopenia in typhoid; the Widal reaction is present in typhoid, not in appendicitis; as a rule typhoid is gradual in onset, accompanied by headache, backache, weariness and sometimes by epistaxis; in typhoid also there will be found enlarged spleen, steady rise of temperature, relatively low pulse rate, the rash, and the typhoid bacilli may be found in the blood.

6. In amputation at the middle third of the leg, the arteries to be ligated are: Anterior tibial, posterior tibial, peroneal.

7. In Pott's disease, the anterior part of the bodies of the vertebræ are most commonly affected. The body of the affected vertebræ is gradually destroyed, and the affection spreads, under the anterior common ligament, to the neighboring vertebræ. As a result of the destruction of the bodies of the vertebræ, the spine bends, and a posterior angular deformity occurs. Pus may form, and caries be found in the affected bodies.

8. OSTEOMYELITIS. Symptoms: Sudden onset; pain, tenderness, fever, chills, swelling of soft parts; sometimes the joint can be moved gently without pain; septicaemia or pyemia may be present.

It is to be diagnosed from (1) Rheumatism, in which more than one joint is affected and the tenderness is in the joint, and not near it. (2) Tuberculous arthritis, in which the onset is slow and the trouble starts in the epiphysis rather than in the diaphysis. (3) Cellulitis, in which the bone and periosteum are not affected, and in which there is always a wound.

Treatment consists in relieving the constitutional symptoms and preventing the bone from necrosing. An incision down to the bone is made; if pus is beneath the periosteum, the latter is also incised; a piece of bone is removed by chisel or trephine, pus is removed, the endosteum is hurt as little as possible, the wound is irrigated with hot bichloride solution and packed with gauze; the soft parts are closed and the wound well drained. In case this fails, amputation may be necessary.

9. The chief bacteria of suppuration are: Streptococcus pyogenes; staphylococcus pyogenes aureus, albus, and citreus; bacillus coli communis; bacillus pyocyaneus, pneumococcus, bacillus typhosus, gonococcus, and bacillus tuberculosis. The streptococcus is the most virulent, and probably the staphylococcus pyogenes aureus the next.

10. The following table, from Eisendrath's *Surgical Diagnosis*, gives the diagnosis:

COMA FROM INTRACRANIAL INJURY.	APOPLECTIC COMA.	UREMIC COMA.	ALCOHOLIC COMA.	OPIUM POISONING.
Deep coma; may have history of onset after fall or injury. Evidence of fracture of vertex or base.	Deep coma; sudden onset. If any injury, only a scalp wound.	Deep coma. Slow onset unless convulsions have preceded the coma.	Can be aroused by supraorbital pressure unless very profound.	Can be aroused unless very deep.
Pupil dilated on side of lesion. Choked disc.	Pupils unequal or dilated. Contracted in hemorrhage into the pons.	Albuminuric retinitis.	Pupils normal or somewhat dilated.	Pupils contracted to pinpoint size.
Pulse very slow.	Pulse full and slow, often arteriosclerotic high-tension pulse.	Pulse rapid.	Pulse more rapid than normal, and full	Pulse rapid, may be irregular.
Respiration slow and stertorous.	Respiration slow and irregular.	Respiration frequent and irregular.	Regular respiration.	Respiration very slow—may be 6 to 8 per minute.
Temperature higher—101°.	Temperature higher on paralyzed side, but lower in rectum.		May be low or normal.	
Urine normal or contains trace of albumin.	Urine contains trace of albumin, but may be same as in uremia.	Urine shows albumin, casts, and low urea percentage.	Normal.	Normal.
Hemiplegia on opposite side to that of injury. If contusion of brain is also present, may have generalized convulsions.	Hemiplegia with convulsions on one side.			

PHYSICAL DIAGNOSIS.

1. Râles: (abridged from *Pocket Cyclopedia*).

VARIETY.	HOW AND WHERE PRODUCED.
Amphoric	By movement of air in a tense-walled cavity containing air and communicating with a bronchus.
Bubbling	By passage of air through mucus in the trachea bronchi, and bronchioles.
Cavernous	By passage of air through a small cavity with flaccid walls, which collapse with expiration.
Crackling, dry.....	By the breaking down of lung tissue.
Crackling, moist.....	By fluid in very small cavities, and finer bronchi.
Crepitant	By passage of air into vesicles collapsed, or containing fibrinous exudation. Usually at the base of the lungs.
Dry	By narrowing of the bronchial tubes from thickening of the mucous lining, from spasmodic contraction of the muscular coat, viscid mucus within, or pressure from without.
Friction	By the rubbing together of serous surfaces, roughened by inflammation or deprived of their natural secretion.
Gurgling	By the passage of air through fluid in cavities, on coughing.
Moist	By the passage of air through bronchi containing fluid.
Mucous (of Laennec)....	By viscid bubbles bursting in the bronchial tubes.
Râle redux, râle de retour.	By the passage of air through fluid in a bronchial tube.
Sibilant	By narrowing of the smaller bronchi from viscid mucus adhering to the walls, from thickening of the lining membrane or spasmodic contraction.

VARIETY.	HOW AND WHERE PRODUCED.
Sonorous	By lessened caliber of the larger bronchi, from spasm, tumefaction of mucous lining, or external pressure.
Subcrepitant	By passage of air through mucus in the capillary bronchial tubes.
2.—	
PLEURISY WITH EFFUSION.	LOBAR PNEUMONIA.
Moderate fever of continuous type; declines by lysis.	Fever, 102° to 104° F.; falls by crisis.
Prostration moderate.	Prostration extreme.
Unilateral distention of the thorax.	Absent.
Countenance pale and anxious.	Mahogany-colored flush of cheeks.
Limited expansion at base of chest on the affected side.	Degree of expansion slightly, if at all, inhibited.
Tactile fremitus diminished or absent.	Increased over area of consolidation.
Interspaces bulging at base of chest.	Absent.
Percussion shows flatness, with great resistance to the pleximeter finger.	Dullness with less resistance, and sometimes a tympanitic note.
Diminished or absent breath-sounds over effusion the rule. Respiration murmur diffuse, distant, and generally unaccompanied by râles.	Harsh bronchial breathing and presence of râles in first and third stages, unless a bronchus is plugged.
Bronchial breathing may be present over the entire affected side of the chest.	
Friction sound heard in early and late stages.	No friction murmur; râles present.

3. *Impacted stone in the right ureter* causes colic, which comes on suddenly and occurs in spasms of excruciating pain, which is referred to the kidney and ureter and to the testis and penis. Collapse, cold sweats, nausea and vomiting, retraction of the testis, frequency of micturition and strangury are present. To differentiate it from *renal colic*, the roëntgen-ray is necessary. "It is diagnosed from *biliary colic* by the absence of jaundice and the localization of pain at a lower level; from *peritonitis*, *appendicitis*, and *intes-*

tinal obstruction by the absence of rigidity of the abdominal walls, distention of the bowels, or stercoraceous vomiting; from *severe lumbago* by the reference of the pain to the urinary organs, and the absence of exacerbations on muscular movements." (Buchanan's *Surgery*).

4. *Physical signs of pyloric stenosis*: There is an abnormal prominence of the epigastric region; a tumor in the region of the pylorus which seems to be connected with the stomach; percussion gives a tympanitic note (if the stomach is empty), extending to or below the umbilicus; if the stomach is full, the note is high pitched; on auscultation, a splashing and rumbling sound is heard.

5. The early manifestations of pulmonary tuberculosis are: (1) *Physical signs*: deficient chest expansion, the phthisical chest, slight dullness or impaired resonance over one apex, fine moist râles at the end of inspiration, expiration prolonged or high pitched, breathing interrupted. (2) *Symptoms*: General weakness, lassitude, dyspnea on exertion, pallor, anorexia, loss of weight, slight fever, and night sweats, hemoptysis.

HYGIENE.

1. *The means of purification of public water supplies* are storage and sedimentation, chemical treatment, and filtration. *Sedimentation*. A part of the impurities in the water may be removed therefrom by storing the water in basins where the suspended matter sinks by the action of gravity, and in the process of settling entangles other impurities, as well as some of the bacteria in the water. In order to get good results, the basins must be shallow, the water left undisturbed, and the accumulated sediment removed from time to time. No complete reliance can be put on this method, as it does not guarantee a germ-free water. *Chemical purification*: The sedimentation of water in the basins may be hastened by the addition to the water of certain chemicals, which act as coagulants and form precipitates, entangling the organic impurities and bacteria, thus freeing the water from a large part of them. Alum (half a grain to the gallon), chlorine, bromine, copper sulphate, metallic iron, and ozone are used for this purpose. Neither sedimentation nor chemical purification are practicable for large water supplies, nor are they free from many objections. *Filtration*: This is the only method which has proved successful in providing a pure water supply. Filtration of large quantities of water is accomplished by means of sand beds of large area, the sides and bottoms of which are concreted, and on the bottom of which are placed numerous perforated and open drains which are to lead off the filtered water into separate special reservoirs. On the bottom of the filter areas, which are usually half or an acre in size, is placed a layer of coarse gravel, upon this a layer of finer gravel, which is then covered by a layer of fine, sharp sand, several feet in thickness, the whole filtering medium being from 4 to 6 feet in thickness. The filter is at first filled from beneath so that all air is driven off, and the filter area is then filled to a level of several feet above the filter bed. A filter of an acre in area may be made to filter two to four millions of gallons of water in twenty-four hours. Such filters act not only mechanically in intercepting all suspended impurities, but the slimy sheet which soon covers the top layer of the sand acts biologically upon the water and destroys a large number of bacteria, so that, it is claimed, the water may be freed from 99 per cent. of its bacteria, provided the rate of filtration is not too rapid and the top of the sand-layers is scraped off half an inch from the surface from time to time. (From Price's *Essentials of Hygiene*.)

2. *Immunity* is insusceptibility, or capacity for resistance on the part of the body to disease or, in the more limited sense, to infection or intoxication or their effects. Immunity may be *natural* or *hereditary*. The absolute or relative insusceptibility of turtles and fishes for tetanus, and of the lower animals for syphilis and for scarlatina, are examples of hereditary or natural immunity. On the other hand, immunity may be *acquired*. Acquired immunity may be secured by an attack of the disease from which the individual has recovered—*natural immunization*. Or immunity may be acquired by the introduction into the body of some material which gradually diminishes susceptibility without inducing distinct disease—*artificial immunization*. (Delafield and Prudden.)

3. "The clothing and bedding which are to be disinfected by means of steam should be carefully wrapped in cloths saturated with 1 per cent. carbolic acid solu-

tion, placed in a wagon, and taken to the disinfecting station. After the bed has been stripped, all refuse matter, paper, and articles of little value are wrapped in cloths saturated with carbolic acid and burned in a stove or furnace. The floor, doors, windows, furniture, and the walls for a distance of 1½ meters from the floor should be washed with 5 per cent. carbolic acid solution. The walls and ceiling of the room should subsequently be sprayed with 1:1000 bichloride of mercury solution. If the walls are papered, it is advisable to remove carefully the paper before beginning the disinfection. The room is then closed as tightly as possible and disinfected by means of formaldehyde." (Bergery's *Hygiene*.)

4. *Essentials for the production and preservation of pure dairy milk*: Vaughan's rules are as follows: "(1) The cows should be healthy, and the milk of any animal which seems indisposed should not be mixed with that from the healthy animals. (2) Cows must not be fed upon swill or the refuse from breweries or glucose factories, or upon any other fermented food. (3) Milch cows must not be allowed to drink from stagnant pools, but must have access to fresh, pure water. (4) The pasture must be freed from noxious weeds, and the barn and yard must be kept clean. (5) The udders should be washed and then wiped dry before each milking. (6) The milk must be at once thoroughly cooled. This is best done in the summer by placing the milk can in a tank of cold water or ice water, the water being of the same depth as the milk in the can. It would be well if the water in the tank could be kept flowing, and this will be necessary unless ice water is used. The tank should be thoroughly cleaned each day, to prevent bad odors. The can should remain uncovered during the cooling, and the milk should be gently stirred. The temperature should be reduced to 60° F., or lower, within an hour. The can should remain in cold water till ready for delivery. (7) Milk should be delivered, during the summer, in refrigerated cans or in bottles about which ice is packed during transportation. (8) When received by the consumer, it must be kept in a clean place, and at a temperature some degrees below 60° F."

5. *Mortality rates* are calculated at so many deaths per 1,000 of the population. The death rate is found by dividing the number of deaths by the number of the population, and multiplying the result by 1,000.

Example: In a population of 4,000 there are 60 deaths, hence the death-rate is

$$\frac{1000 \times 60}{4000} = 15 \text{ per 1,000 of population}$$

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

HYSTERIA AND ACCIDENT COMPENSATION. By FRANCIS X. DERCUM, M.D., Ph.D. Published by the George T. Bissel Company, Philadelphia. 120 pages.

PRINCIPLES AND PRACTICE OF MEDICINE. By ARTHUR R. EDWARDS, A.M., M.D. Published by Lea & Febiger, Philadelphia and New York; 1022 pages; illustrated with 80 engravings and 23 plates; third edition, thoroughly revised, and rewritten.

BEING WELL-BORN. By MICHAEL F. GUYER, Ph.D. Published by The Bobbs-Merrill Company, Indianapolis; 374 pages; illustrations. Price, \$1.00.

HYGIENE AND SANITATION. By SENECA EGBERT, A.M., M.D. Published by Lea & Febiger, Philadelphia and New York; 525 pages; illustrated with 141 engravings and 5 plates.

URGENT SURGERY. Vol. 2. By FELIX LEJARS. Translated from the Seventh French edition by William S. Dickie, F.R.C.S., and Ernest Ward, M.A., M.D., F.R.C.S. Published by William Wood & Company, New York; with 588 pages; 1086 illustrations and 20 full-page plates. Price, \$7.00.

TRANSACTIONS OF THE AMERICAN PEDIATRIC SOCIETY. Vol. 27. Edited by Linnaeus Edford La Fetra, M.D. American Medical Association Press, Printers, Chicago. 365 pages; illustrations.

THE SPRINGS OF SARATOGA—THEIR VALUE IN THE TREATMENT OF DISEASE.*

BY W. GILMAN THOMPSON, M.D.,

PROFESSOR OF MEDICINE IN THE CORNELL UNIVERSITY MEDICAL
COLLEGE IN NEW YORK CITY

IN the library of this academy may be found upward of thirty works, both books and pamphlets, upon the subject of the Saratoga Springs. The most notable among them, not only for its priority but for extraordinary elaboration of chemical detail, is the book by that distinguished surgeon to the New York Hospital, Dr. Valentine Seaman, called "A Dissertation Upon the Mineral Waters of Saratoga." This book, published originally in 1779, or 137 years ago, was followed by a second edition in 1809, which was enlarged to 131 pages. Besides a geological map and physiographic description of the location of the Springs, a series of chemical experiments made by the doctor himself is recorded with minuteness, and, when one considers the general crudeness of the chemical analytical methods of more than a century ago, the observations of Dr. Seaman are truly remarkable. In his analysis of the waters such reagents were employed as lead acetate, silver nitrate, ammonia, sulphuric acid, lime water, litmus and turmeric, and he concludes from the effects of these and other reagents that "the waters contain carbonic acid, carbonate of iron, lime supersaturated with carbonic acid, muriatic salt, carbonated alkali and magnesia and a sulphurous impregnation." Methods of evaporation, distillation, and precipitation are described, and there is a complete study of the temperature and other physical properties of the waters. Thereafter follow chapters upon "the use and medicinal virtues of the waters," and while recommending them for "dyspepsias," "rheumatisms," gravel, scrofula, and many other disorders, the good doctor reaches the temperate conclusion that "an universal remedy is a perfect solecism." The book concludes with a comparison of "the artificial mineral waters as prepared in this city" (New York).

Another interesting book, entitled "An Experimental Inquiry Into the Chemical Properties and Medicinal Qualities of the Principal Mineral Waters of Saratoga," was published in 1817 by the famous Dr. William Meade of Philadelphia. In this work still more elaborate chemical analyses are recited in detail, and the author states that "many of the conclusions which are drawn by Dr. Seaman are correct and judicious," while "to him, more than any other writer, are we indebted for much important information." Dr. Meade dwells upon the benefits derived both from drinking the waters and bathing in

them, in cases of nephritis, gravel, diseases of the liver, chronic skin diseases, and many other ailments. Speaking of their use in gastric disorders he naively remarks that: "In Boston, in particular, of late years a disorder has prevailed to which the faculty have given the name of dyspepsia; to doubt the propriety of which would seem to be an instance of some presumption" (!) He also dwells at length upon a comparison of the Saratoga waters with those of many foreign spas.

Comment often has been made by our foreign colleagues, while visiting this country, upon the comparative apathy of American physicians toward hydrotherapy in general, and to a great extent this would seem justified. Little attention is given to the importance of this subject in the teaching in our medical colleges, our medical literature gives it scant space, and many an otherwise well assorted physician's library is found to contain no work upon balneology or hydrotherapy. It may fairly be stated that few, if any, among our more noted spas have attained the completeness of development or achieved the reputation for serious and thoroughly scientific treatment of disease comparable to that of a score and more of such health resorts in Europe, and several of them, indeed, are little more than resorts of fashion, in which real hydrotherapy is a secondary consideration. And it is further true that while the well-to-do with the means and leisure for extensive travel may here and there command scientific hydrotherapy, the poor in our cities find almost no public establishment for the proper conduct of this therapeutic measure.

It is therefore most gratifying that the State of New York, which has taken the lead in the conservation of its natural resources by reforestation, establishing State parks, guarding its streams, stocking them with fish and protecting its game, should now have rescued for all time one of the most unique and valuable groups of mineral springs which is anywhere known, and placed it beyond the reach of commercialism.

For many years a multitude of those suffering from chronic ailments have sought relief at foreign spas, often with considerable inconvenience and expenditure of time and money. Patients with advanced cardiovascular diseases, renal diseases, gastrointestinal disorders, nervous disorders and a variety of other disease conditions, have had the waters of these spas applied both within and without, and have acquired such belief in their efficacy that, in many instances, they have returned year after year to their favorite bath cure, where they have either drunk the mineral waters or bathed in them, or both, and taken such accessory treatment as their particular resort afforded. We have all seen, from time to time, cases which have strikingly been improved by such procedure. The skeptical among us have attributed this benefit to factors

*A paper read before the New York Academy of Medicine, February 17, 1916.

other than the waters themselves, such as the ocean voyage, the differences in climate or altitude, the novel environment, the freedom from cares which may result from long distance from home, the amusements afforded, and even to the difference in language forced upon one's attention. But those of us who have given serious study to the subject are convinced that, while all these things may be contributory, there is great gain to be derived from the properly directed use of mineral waters. I confess to having for a long time belonged to the first group of critics, but a personal study of a number of the leading foreign spas was converting to the belief that not only is there peculiar virtue in these waters, but that to be of maximum benefit they must be drunk or bathed in at their source. The difference is subtle, but it is nevertheless definite. Vichy, bottled and transported, may still be vichy, but it is not like vichy at its source, and the original Congress or Hawthorne water bottled, was never quite like the same waters taken at the Saratoga Springs. This common experience suggests an analogy between canned and fresh food. Canned vegetables one may live on for a time, but there is no "uplift" in them for a dyspeptic, although chemical analyses and physical tests may reveal no essential difference from the same food when fresh, nor is the superheated or canned air of elaborate closed ventilation systems the optimum air for an invalid to breathe. In the case of mineral waters, it has been asserted that radium emanations were in great part responsible for the peculiar properties which they exhibit at their source, and it is conceivable that there are further physical or chemical factors which are as yet unmeasured by science. Such was the case with the atmospheric air, the composition of which was, for a long time, confidently believed to have been determined completely until argon, helium, and similar new elements were found to exist in it.

It does not now seem probable that the continental spas of Europe will be open freely to invalid Americans for a long time to come, and the moment is therefore opportune carefully to consider what substitutes may be utilized at home. Where may we best send for spa treatment cases of chronic myocarditis and endocarditis, advanced arteriosclerosis, chronic rheumatism, or other forms of arthritic disease, obesity, chronic nephritis, neurasthenia, and other nervous disorders?

This country, like Europe, is richly endowed with mineral springs, whose waters, speaking collectively, may be found, upon chemical analysis, to duplicate those of any noted foreign spa, as any European climate may be duplicated here. In the waters of Saratoga there are found a variety and strength of certain ingredients which may even surpass the foreign waters of similar character, such ingredients particularly as carbon dioxide, the alkaline salts and iron. And in the climate of Saratoga there are clearness, dryness, uniformity, and a general salubrity which leave little to be desired. These facts have long been known, but unfortunately for various reasons, the advantages of this resort have not, until very lately, been fully appreciated scientifically, and the medical profession has fallen quite out of the habit of utilizing them. I take it that the object of this meeting is, so to speak, to reintroduce Saratoga and call attention to the possibilities which exist for utilizing a "definite treatment for definite disorders," as Dr. Ferris has stated, at a spa of exceptional attractiveness and potentiality which lies within our own gates. It is my purpose pres-

ently to point out these definite disorders which may now receive definite treatment there.

The Saratoga Springs have undergone a very interesting development which might briefly be summarized as comprising successive phases of evolution, dissolution and resolution—or re-solution—of the waters. There is ethnological and geological evidence that the waters were utilized by the Indians more than three centuries prior to the historic voyage of Columbus, and in early Jesuit records there is mention of a priest of that order who visited the Springs with the Indians in 1643. The real evolution of the Springs began more than two generations past, when their ease of access, attractive surroundings and increasing reputation made them a resort of fashion and place of summer recreation for many years. This was in the days when the so-called "summer resorts" were few and means of travel much less highly elaborated than at present.

Factors such as these enhanced the popularity of Saratoga to an extraordinary degree, attracting there all classes of pleasure seekers, until amusement was more sought than considerations of health, and horse racing, gambling and similar diversions reached a climax far in excess of that anywhere else in the country. It is true that the waters, particularly the laxative ones, were drunk, but quite in haphazard manner, often in excess or too great variety, and other waters were bathed in to a limited extent, largely with the mistaken idea that the mineral salts were absorbable through the skin. Gradually the fashionable element moved away to new resorts. the famous fashion or "peacock parades" of the broad hotel verandas disappeared, and dissolution began. This period was completed by the increasing economic use of carbonic acid gas which was withdrawn from the springs by commercial companies in such quantity that the solubility of certain elements of the waters was hopelessly impaired, and the pressure under which they sought the surface seriously lessened. The period of re-solution followed when the State was induced to take over the control of the springs and permit nature to restore them to all their original potency through redissolving the ingredients of the waters. It is indeed the method of State and municipal control which has placed the principal European spas upon their high plane of efficiency.

Upwards of 1600 American patients a year have been in the habit of going to Nauheim, mainly for treatment for myocarditis, chronic valvular heart lesions, angina, arteriosclerosis, and other cardiovascular conditions. It has been proven at Nauheim that the chief value of the alkaline saline baths was their supersaturation with carbonic acid gas to the extent of 25 per cent, but the report of the consulting engineer for the State at Saratoga, Mr. C. G. Anthony, has shown 33 per cent in the waters of the High Rock Bath House. There seems, therefore, no reason why this group of diseases may not ultimately be treated as successfully at Saratoga as at Nauheim. The elevation at Nauheim is about 450 ft. above the sea, that of Saratoga is 300 ft., and Saratoga, like Nauheim, abounds in fine trees and borders on mountain ranges. Arrangements have been completed, moreover, for the laying out of carefully graded walks on which the patient may take the Stokes-Oertel "Terrain Kur," the value of which is so much emphasized at Nauheim in the treatment of cardiovascular diseases and obesity.

The waters of Nauheim were used for drinking in nervous and digestive disorders long before the

value of their carbonic acid as a cutaneous stimulant was proven by the baths, and those of Saratoga present great variety and potency for drinking purposes. In fact, this use should be emphasized particularly as being in many conditions of equal or greater value than their bathing properties.

Wiesbaden and Baden-Baden are much resorted to by those afflicted with chronic arthritis, sciatica, neuralgias, and other nervous disorders, gout, rheumatism, chronic cystitis, and nephritis. Those of you who have visited these resorts may recall their attractive "Trink-Halles" and the importance which is given to the drinking of the waters as well as bathing in them. Their waters are in many respects quite similar to some of the Saratoga Springs, with the exception that those of Wiesbaden are hot, not cold, as at Saratoga; nor does the latter contain the arsenic of the Baden-Baden Kur. Certainly, from analogy, this group of diseases should derive benefit from the Saratoga waters, nor is analogy unsupported by direct experience, for such cases long ago were dealt with successfully there by potations, as testified in the writings of Seaman, Meade, and very many other experienced clinicians.

Kissingen, which is visited annually by upwards of 34,000 patients, has acquired a well-deserved reputation for the beneficial treatment, particularly of chronic catarrhs of the gastrointestinal and respiratory systems, cystitis, anemia and obesity, and one of its chief resident chemists, Dr. Paul Hoertl, the Director of the Royal Chemical and Balneological Laboratory at Bad Kissingen, has declared that from analyses the Saratoga waters should be capable abundantly of accomplishing similar results when systematically drunk.

At Ems the like diseases are treated with alkaline chloride and chalybeate waters, both of which may be furnished at Saratoga in greater strength.

Dr. Simon Baruch has pointed out the close analogy of the Saratoga Hawthorne Spring No. 2 with that of the Grande Grille of Vichy, which latter has proved of much value as a diuretic in renal and vesical diseases, chronic rheumatism and chronic skin diseases.

The many different springs of Saratoga which may be drunk fall naturally into three general groups, in each of which a half-dozen or more of the most active and copious springs are included. These are (1) the saline laxative group typified by the long familiar Hathorn and Congress waters; (2) the alkaline-saline group, typified by the Geyser spring, in the waters of which alkalinity is the essential feature, together with medicinal quantities of iron and lithium, and (3) the alkaline-iron or chalybeate springs, typified by the Karista, which yields a strong excess of ferrous carbonate. All of these waters are copiously charged with natural carbonic acid gas, which renders them more palatable and efficient, and, in such of them as are used for bathing, excites distinct cutaneous reaction. In detail, as shown by the analyses of the laboratory of the State Commissioners of the Reservation, they contain five chlorides, six bicarbonates, a bromide and iodide, and include such alkaline earths and metals as magnesium, lithium, strontium, iron, and manganese in addition to several ingredients of lesser value. With the exception of sulphur they may be said to include all of the important mineral or inorganic chemical ingredients of the body, and their drinking affords opportunity for the replacement or renewal of these ingredients, as well as for added solvent, diuretic, and evacuant effects.

The saline laxative or aperient waters of the Congress and Hathorn No. 1 springs are those upon which the more than national reputation of Saratoga Springs was first built more than a century ago, and at one time they were exported to foreign countries in considerable quantity. Their laxative effect is due to a high percentage of bicarbonate of magnesia, together with sodium sulphate and other salts. Their usefulness when drunk is in cases of chronic constipation, hepatic congestion, cirrhosis, chronic arthritis, arteriosclerosis with high tension, obesity, gout, diabetes and similar disorders of metabolism. They act without griping, and may be continued in proper dosage for a considerable period of time.

The second group of alkaline-saline waters derive their virtue from their antacid effect, and have therefore been found beneficial in gastrointestinal catarrhs, hyperacidity of the gastric contents, rheumatism, goutiness, lithemia, gravel, neuralgias, neuritis, chronic generalized skin diseases, and the like affections. The active spring of this group, known as the Geyser, equals in flow that of the French Vichy, which it also resembles in type. Its water, being highly diuretic, may prove useful in reducing high blood pressure in cases of arteriosclerosis.

The third group, known as the alkaline-ferruginous or chalybeate waters, were the first springs to be exhausted by the gas pumping process. Among them, however, the Columbia spring has been restored, and a new well has been opened whose waters have been found to be the strongest natural iron waters known. Their use may prove valuable in cases of chronic anemia and retarded convalescence from numerous disorders.

Thus it is seen that from the standpoint of medicinal drinking waters alone Saratoga is capable of supplying the needs of almost any case which is likely to be improved by such agencies, and are well worthy of trial, for such cases as heretofore have been sent in large numbers to Vichy, Marienbad, Kissingen, Homburg, and similar foreign spas.

The influence of radium emanations in drinking waters is not yet fully established, but there is a growing belief in their efficacy in the treatment of arthritic and digestive disorders. The United States Bureau of Mines, in course of an investigation of all the important mineral springs of this country, found that all the Saratoga springs are radioactive, although complete quantitative determinations have yet to be made.

Turning now to consideration of the bathing opportunities afforded by the springs of Saratoga, it is noted that their first use for this purpose was for the treatment of chronic skin diseases, particularly those associated with gout and rheumatism. Their effect may be enhanced by the simultaneous employment of appropriate waters taken internally, an advantage which Saratoga possesses in decided degree over Aix-les-Bains, for example, with its feeble Deux Rennes single drinking fountain.

Arrangements have been made, moreover, for the introduction of the mud bath, or moor bath, which in foreign spas such as Borneo, Leuck and many others, is so extensively employed in the treatment of chronic eczema, psoriasis and other generalized cutaneous eruptions.

The Saratoga baths have also been successful in the treatment of periarticular thickening, ankylosed joints, myalgia, gouty joints, sciatica, lumbago and allied affections. In such conditions, however,

much depends upon coincident massage, douching under water pressure and proper thermic regulation, details which it is hoped in time may receive proper emphasis in the newly constructed bath houses.

Probably the greatest reputation of the Saratoga baths is yet to be won in the development of the carbonic acid saline bath, as it affects particularly cardiovascular diseases, arteriosclerosis and obesity. The effects of such baths upon the peripheral blood vessels and nerves by increasing the capacity of the cutaneous capillaries, relieving the overstrained heart muscle and generally regulating the circulation in congested viscera are too well known to need recapitulation here. That this valuable method of treatment has heretofore been so little developed in this country is due to the fact that the only natural mineral waters in this country east of Colorado Springs, which are saturated with carbonic acid gas, are at Saratoga. I have already alluded to the comparison between the Saratoga waters and those of Nauheim. Now that the former crude and unscientific use of these domestic bathing waters, exploited as they were merely for temporary gain, is being replaced by intelligent management and State control, with the idea of permanence and real use to the medical profession, it will be strange indeed if they do not rapidly grow in popularity and usefulness. The State Commissioners are fully appreciative of this great opportunity, as shown by the statement in their annual report of 1914 that "The carbonic acid gas is one of the most important therapeutic agents in mineral waters, whether used for drinking or bathing, and in respect to this Saratoga Springs is easily first." They further point out that the investments in similar bathing establishments in Europe exceed \$50,000,000, all of which have been "paying handsome returns on the investment."

It has been the experience at all the noted foreign spas that there are many accessories which are demanded in order to insure the success and popularity of these health resorts. Many of these spas are in such near geographical relationship, like Nauheim, Schlangenbad, Langen-Schwabach, Wiesbaden, Homburg and Baden-Baden, for example, that no doubt an element of rivalry or competition has necessitated somewhat extravagant expenditure, as for example in the new million dollar bath house at Kissingen. From such rivalry Saratoga, owing to its unique position, is quite free. Nevertheless, attractive bathing rooms and drinking halls, facilities for manual and mechanical massage, for electrical treatment, Zander apparatus and rooms fitted with appliances for using the waters in douches, irrigations, sprays and gargles, are all accessories which should not be dispensed with in any first-class watering place, and the Saratoga Commissioners are quite ready to install them on a proper scale as fast as the State is willing and able to supply the necessary funds. Of desirable hotels there is already no lack, and the natural beauty of the grounds about the Springs needs but comparatively small expenditure to enhance it. The Geyser Park, for instance, comprising some 250 acres, presents a charming diversity of woods, ravines and streams, with a waterfall and lake. Many thousand additional trees have already been planted, and pleasant walks abound. There is an abundance of good potable water for table use and two outdoor swimming pools have been constructed, which recall in attractiveness that of Glenwood in Colorado.

The soil of Saratoga is porous, and the climate is

characterized by dryness and freshness, and what, for this region, is an exceptional number of sunshiny days, the meteorological records showing that fully two-thirds of the days of the year have complete or partial sunshine.

An important consideration affecting the future popularity of the Saratoga Springs is the very abundant supply of waters which they yield, in contrast to certain springs elsewhere in this country and abroad, where the development of the waters has necessitated the sinking of deep and costly wells to augment the original supply. In Kissingen, for example, it was found necessary to sink an artesian well to a depth of 3000 ft. at a cost, with equipment, of \$75,000. At Saratoga, on the contrary, the waters rise easily from a depth below the surface of only 150 to 600 ft., and the Commissioners state that it may prove desirable to close about 100 springs in order the better to handle the output of the remainder. Moreover, fifteen years of pumping, which at times amounted to withdrawing a half million gallons of water a day to obtain the carbonic acid gas, has only temporarily interfered with the water flow, which rapidly returned to normal when the destructive process was stopped. There need be no doubt, therefore, that the supply of waters at Saratoga will not only meet all reasonable demands for local drinking and bathing, but permit of the bottling of certain of the waters for use elsewhere, as in former times.

In comparing the Saratoga waters with those of so many foreign spas, one should make no claim for them as a "cure-all." Far from it, for the matter has not yet been thoroughly enough investigated from a modern scientific medical point of view. Nevertheless, it is amply proven that the number and variety of the springs is exceptional, that the supply of waters for both drinking and bathing, as redeemed by the State, is now abundant, the climate and surroundings are in every way attractive and propitious, and the resort is most accessible.

It would seem, therefore, that if the medical profession will co-operate with the State in the full development of the resources of the Springs for the benefit of properly selected cases, results may ultimately be obtained fully comparable to those of the most successful foreign spas. No doubt many invalids who have had what might be termed the "foreign spa habit," and who, since the war, have bitterly complained that "there is no place to go but home," may find that "home" can offer them some exceptional advantages after all!

61 WEST FORTY-NINTH STREET

THE SURGICAL TREATMENT OF GASTRIC AND DUODENAL ULCERS.*

BY GEORGE WOOLSEY, M.D.

NEW YORK

THOUGH my remarks are chiefly concerned with the treatment of gastric and duodenal ulcers, a word or two, by way of preface, in regard to the diagnosis. This has become much more exact since we have been able to confirm or correct our clinical diagnoses by the operative findings in a large number of cases. The history is still the most reliable means of diagnosis at our command. In my experience typical cases do not form such a large proportion of cases met with as in the reports of the Mayo Clinic, but

*Read before the New York Clinical Society, March, 1915.

more nearly equal in number atypical cases. The diagnosis of typical cases is easy from the history alone, but even they are sometimes very closely simulated by extra-gastric conditions giving gastric symptoms, especially chronic appendicitis, gall bladder conditions, chronic pancreatitis, etc. It is much more difficult to diagnose these conditions from gastric and duodenal ulcers with an atypical history. In general, duodenal ulcers give a typical history, with hunger-pain and food relief, much more often than do gastric ulcers, and pyloric ulcers are more constantly typical than ulcers further from the pylorus. As aids in the diagnosis, not as sufficient in themselves, we employ gastric analysis and the x-ray.

Not only does the gastric analysis vary greatly in typical as well as in atypical ulcer cases, but various conditions simulating ulcer may give analyses, many features of which strongly suggest ulcer. The disturbance of the mechanics of the stomach is of more diagnostic value than that of its chemistry. That is one reason why the x-ray is becoming more valuable than the laboratory analysis. But the use of the x-ray to demonstrate disturbance of gastric motility gives only indirect evidence. More and more it is furnishing direct evidence of ulcer or new growth by showing filling defects, the niche of a penetrating ulcer, the crater of a deep ulcer, as well as interference with peristalsis and changes in the form, size, and position of the stomach, and the spastic incisures opposite some ulcers.

It may be a difficult problem to differentiate between many cases of gastric and duodenal ulcers and the several conditions which simulate them. Hence, though we operate with varying degrees of confidence in our diagnoses in different cases, the operation is practically always exploratory at the outset, at least to some extent.

Medical treatment with rest and careful diet, with or without alkalies, atropine, etc., should always be thoroughly tried. Acute ulcers will nearly all yield to treatment and, except for perforations, do not call for surgical treatment. The symptoms due to chronic ulcer will subside with or without treatment, after a time. Proper treatment will hasten their disappearance. But relapse is the rule and there is some question whether medical treatment gives a permanent cure. Mayo stated¹ in 1911, "We have operated in a great number of cases where the symptoms were in abeyance, and it might be thought that the patient was cured, but I have never seen one in which there was definite closure of the ulcer." But if cure follows gastroenterostomy it would seem possible to effect cure by persistent medical treatment, at least in some cases. When, after pyloric stenosis or long-continued gastritis, the acidity becomes lowered, chronic ulcers may cicatrize. In one case I excised an indurated cicatrix on the lesser curvature, which showed no ulcer on gross or microscopic examination. But though admitting the possibility of cure of calloused ulcers, without operation, and advising medical treatment before operation is considered, I regard a so-called medical cure as only temporary in the vast majority of cases. The cases operated on have had one or more "medical cures" and many have relapsed repeatedly. The average hospital patient is not as susceptible as private patients to medical treatment, on account of the lack of time and means to give to it.

After two or more relapses have occurred, in spite of treatment, something more is required to relieve these patients of recurring attacks, with the

loss of time, flesh and strength, the danger of pyloric stenosis or adhesions, which render the symptoms continuous, and especially to avoid the risk of perforation, hemorrhage, and malignant degeneration.

Gastroenterostomy is the commonest, simplest, and safest method of surgical treatment for ulcer. It affects both the drainage and the chemistry of the stomach, diminishing the acidity by the presence of a small quantity of bile and pancreatic secretion, relieving the pylorospasm and allowing the stomach to empty without irritation of the ulcer by the passage of food. It thus allows the ulcer to heal, and it does so in over 82 per cent. of cases (Paterson²). In this way the conditions just enumerated are relieved, except those due to adhesions or malignant degeneration. Before the ulcer heals, and in case it does not heal, perforation or hemorrhage may occur and gastroenterostomy is not a sure preventive of either, but greatly diminishes the probability of their occurrence. v. Eiselsberg reports³ seven cases in which death occurred from hemorrhage or anemia, due to repeated hemorrhages, after gastroenterostomy, among 334 cases. He remarks: "Thus it will be seen that gastroenterostomy in some cases not only did not stop the hemorrhage but apparently induced it."⁴

It is generally conceded that no operation should be done unless we can see or feel an ulcer. But in a few cases, where the symptoms were typical and no ulcer or extra-gastric condition could be found, the question has arisen in my mind whether one could be overlooked. It seems unlikely that a chronic gastric ulcer could escape notice, except under rare circumstances, but ulcers of the anterior duodenal wall differ pathologically from gastric ulcers on account of the anatomical structure of this part, as pointed out by Payr.⁴ The ulcers here are often small, superficial, with little induration and may appear as a mere erosion or fissure. It is quite possible that such ulcers may be overlooked and search should be made for the not infrequent contact ulcer on the posterior wall, which is more indurated and of the gastric type. In this connection Mayo says:⁵ "On several occasions we have examined the stomach and duodenum through an abdominal incision without finding any evidence of ulcer, and the continued symptoms for some months led to a second exploration, when an ulcer was discovered. Either the ulcer had been overlooked at the primary operation or it had been confined to the mucous membrane and the musculo-peritoneal coats were involved later."

The class of cases giving the best late results are those where the pylorus is stenosed. Under this class in the Mayo Clinic 71 per cent. of duodenal and 67 per cent. of gastric ulcers were cured, and 94 per cent. of duodenal and 92 per cent. of gastric ulcers cured or greatly improved.⁶ Various forms of unilateral pyloric exclusion reproduce this condition of stenosis and are at present much employed, in conjunction with gastroenterostomy, in ulcers of the duodenum and those near the pylorus. Of the various methods I have employed (1) v. Eiselsberg's, the most radical, in which the stomach is divided proximal to the ulcer and both ends sutured; (2) Wilms', in which a band of fascia half an inch wide is fastened tightly around the stomach, proximal to the ulcer, and (3) the method of infolding the pyloric end by suture.

In one of my cases gastroenterostomy failed to relieve the symptoms of a duodenal ulcer, though

the continued symptoms were probably due to adhesions rather than to the ulcer, which had apparently healed. Here v. Eiselsberg's method of exclusion was used, which freed the stomach from the adherent area and resulted in a cure.

The other two methods I have employed in a number of cases with excellent results symptomatically. I have had *x*-rays taken after two or three weeks and all seemed to show that the pylorus was not absolutely occluded, but fluoroscopic evidence of permeability must be added to that of *x*-ray plates to be of value. But perfect occlusion is not necessary in order to obtain a functional rest and cure of the ulcerated area. Even the complete v. Eiselsberg exclusion does not positively insure against hemorrhage. v. Eiselsberg reports,⁵ among thirty-six cases, one patient who suffered from repeated attacks of hemorrhage after a unilateral exclusion. Thus no method, so far considered, gives absolute security against hemorrhage. Contrary to the results of Cannon and Murphy's experiments on animals, I believe that in the human subject the gastroenterostomy opening functionates when the pylorus is open. I have demonstrated this by *x*-rays taken some time after operation. Hartmann claims that this is the case when the gastroenterostomy is in the pyloric portion.

Owing to the fact that duodenal ulcer almost never undergoes malignant degeneration, gastroenterostomy, with or without pyloric exclusion, is the operation of choice and is almost universally practised, with excellent results, though W. J. Mayo has reported a considerable number of excisions of these ulcers, followed by Finney's gastroduodenostomy or by gastroenterostomy.

The case is different in calloused gastric ulcers, which not infrequently become malignant. It may be quite impossible at times to differentiate between an indurated ulcer and a carcinoma, and I have done gastroenterostomy in a supposedly hopeless case of gastric cancer, where the ultimate cure demonstrated it to be a simple ulcer. Among 143 cases of gastroenterostomy for supposed carcinoma in the Utrecht Clinic,⁷ 30 were alive 3 to 11 years after operation, proving the condition to be indurated ulcer. On the other hand in his series of 317 recoveries in 334 cases of gastroenterostomy for ulcer of the stomach and duodenum, v. Eiselsberg reports 13 deaths from cancer of the stomach, among 41 cases which died at a later date, the cause of death being known in only 23. Several of the remaining 276 patients will presumably die of cancer.

This is strongly opposed to the views of Paterson, who states² that his own experience coincides with that of Kocher and Gressot, that less than 3 per cent. of the patients on whom gastroenterostomy is performed for simple ulcer die later of carcinoma. Theodor Kocher believes that early gastroenterostomy is the surest means to prevent the malignant degeneration of ulcers by the cure of the latter.

The material obtained from operated cases in the Mayo Clinic showed that over 60 per cent.⁸ of the cases of carcinoma of the stomach were developed on the base of a chronic ulcer, and a clinical study showed that 60.5 per cent.⁹ of cases of cancer gave a long previous history of gastric ulcer, 43.8 per cent. a typical ulcer history, and 18.7 per cent. a history of irregular gastric ulcer. Payr found 26 per cent. of cancers developed from ulcer in his resected material, and Kuttner 43 per cent.⁴ In general we may suspect ulcers larger than a 25-cent piece of being or becoming malignant.

Whether we accept the lower or higher figures, we must admit that there is a real danger of cancerous degeneration of chronic gastric ulcer, which is much diminished but by no means eliminated by gastroenterostomy. This is a cogent reason for some more radical operation for indurated gastric ulcers. An additional reason, which has even more weight with some, is the difficulty, already referred to, of differentiating between a calloused ulcer and a carcinoma, even after we inspect and palpate the stomach on operation. Another reason for the radical removal of a chronic ulcer, remote from the pylorus, is the fact that such ulcers are cured by gastroenterostomy in a much smaller percentage of cases than are pyloric and duodenal ulcers, according to Payr in about 50 per cent. only.

Two complications of gastroenterostomy, *circulus vitiosus* and peptic jejunal ulcer, usually of the stoma, may be cited as objections to this operation. *Circulus vitiosus* is due to a fault in the technique, is not common, and I have never encountered it in a considerable experience. Peptic jejunal ulcer may also be due to faulty technique. Mayo attributes it to the suture ulcerating through along the margin of the stoma. I have met with it in only one case, where the stomach was resected for carcinoma in a syphilitic patient.* Payr attributes the stenosis of the gastroenterostomy opening to peptic ulcer at this point. To obviate the danger of any harm that may result from the suture I now use only fine chromic gut for both suture layers.

Of the more radical operations for gastric ulcer we have excision, pyloric resection and mesogastric resection.

Excision of the ulcer and suture of the opening may be a very difficult operation, especially in the saddle-ulcers extending well onto the posterior surface with considerable induration or with many adhesions. Excision alone is not enough. It, or the resulting cicatricial contraction, may result in stenosis of the outlet of the stomach, especially if the ulcer is not far from the pylorus. If it does not stenose it, excision is liable to distort the stomach, kinking the lesser curvature and interfering with the motility of the stomach. This is increased by the resulting adhesions. Excision does not relieve the pylorospasm or the hyperacidity. I have found it necessary to reoperate and add a gastroenterostomy, and this should be added in all cases, as Mayo, Payr and many others have pointed out. On the whole, excision is not a satisfactory operation and had better be replaced by one of the forms of resection, when the latter are not decidedly more difficult or dangerous. Resection is a more radical operation and often an easier one than excision and is not open to the same objections. Rodman advised this operation many years ago.

In ulcers of the pyloric region of the stomach, comprising the majority of gastric ulcers, the Billroth method is the operation of choice, followed by gastroenterostomy, or the Polya-Reichel modification in which the proximal end of the stomach is sutured directly to the jejunum. The chief technical difficulty is due to adhesions, especially in case of a penetrating ulcer.

*I recently operated on a patient for supposed peptic ulcer of the stoma, on whom I had done gastroenterostomy for duodenal ulcer 2 years before. No ulcer was found but the linen suture was hanging from the opening. This and considerably more within the wall was removed and the patient has so far been relieved of the symptoms. There was some contraction of the stoma which readily admitted the finger.

When the ulcer is further from the pylorus, usually on the lesser curvature, the mesogastric resection, or resection in continuity, is the operation of choice. The ulcer, and the section of the stomach below it, is resected through the greater curvature. By cutting the pyloric side obliquely the two sides can be made of nearly equal length, so that suture is easy. v. Eiselsberg⁹ recommends supplementing the longitudinal with a transverse incision of the abdomen to get plenty of room, and Payr⁴ advises the free mobilization of the stomach, especially on the lesser curvature and particularly in the thickened indurated part of the gastrohepatic omentum. The stomach is an elastic organ and the bringing together and suture of the two sides of the incision is easier than one would suppose. Owing to the division of the nerves, pylorospasm is avoided and no gastroenterostomy is required. v. Eiselsberg, Payr, Kümmel, and others are enthusiastic in its praise and have reported excellent clinical results and no mortality.

The subsequent x-ray in a case I operated on by this method looked at first like an hour glass stomach, but fluoroscopic examination showed that the appearance was deceptive, the entire pyloric portion being narrow and small. The stomach was emptied promptly. The postoperative course was perfect, no pain or nausea, only hunger was complained of. Kümmel reports that the x-ray in the majority of his cases showed an hour-glass appearance, which he regards as spastic, with very rapid emptying of the contents and extremely good clinical results.

Of course, the mortality of resection is greater than that of gastroenterostomy, which in ulcer is very low (not over 2 per cent.), but the operation is surprisingly well borne and the mortality is not high. Still the difference is enough to raise the question whether the more dangerous operation should be undertaken as a routine or should be restricted to those cases of markedly indurated ulcer where there is some question, however slight, whether malignancy may not exist. The ease or feasibility of resection, without great difficulty and increased risk, and the general condition of the patient has an important bearing on this question. To justify this operation its mortality should not be as much greater than that after simple gastroenterostomy, as the occurrence of carcinoma after the latter is greater than after resection.

The appendix should be examined and removed if any abnormality exists. Moynihan advises its routine removal. In the Mayo Clinic the appendix showed sufficient evidence of disease to justify its removal in 25 per cent. of cases of duodenal and in 16 per cent. of cases of gastric ulcers.¹⁰ In all cases of gastric or duodenal ulcer the patient should be put on a special diet for some time after operation. I employ either a Lenhartz or a modified v. Leube diet. For some time thereafter a careful diet should be advised. The diet is especially important if the ulcer has not been removed or if unilateral exclusion is not employed. Hyperacidity should be kept reduced by alkalis.

One result of the cicatricial contraction of a gastric ulcer at a distance from the pylorus is the formation of a so-called hour-glass stomach. In the x-ray plate the appearance of an hour-glass stomach may be simulated by a deep incisure of a spastic nature opposite an ulcer of the lesser curvature. I have found in one case that an apparent hour-glass stomach was largely due to perigastric adhesions.

The principles of treatment of an hour-glass stomach are the same as those of calloused ulcers. Gastroenterostomy gives good results and should be applied to the cardiac pouch. Gastrogastrostomy has also given good results, but is less certain than gastroenterostomy. In order to remove the dangers of malignant degeneration, as well as to radically cure the condition, mesogastric resection is the operation of choice in suitable cases.

Two complications of gastric and duodenal ulcer may be briefly referred to in closing, *i.e.* hemorrhage and perforation.

Sudden acute hemorrhage, not preceded by dyspepsia, is almost always due to acute ulcer and is best treated medically. Few agree with Dieulafoy that one should operate during the first hemorrhage, if half a liter of blood is lost or if it is repeated within 24 hours. The hemorrhage causes collapse which is favorable to the arrest of hemorrhage, not for operation. The initial hemorrhage from a chronic ulcer is less apt to be so severe, but more apt to be repeated. I have had one case of chronic gastric ulcer, about to be operated on the following day, in which a profuse recurrent hemorrhage proved fatal in half an hour, but such accidents are not common.

When recurring hemorrhages occur and threaten to produce a severe anemia operation should be done before the anemia becomes grave.

In any case of dangerous hemorrhage we have a most excellent means of saving life in direct transfusion. I have employed it with great satisfaction to render a case of chronic ulcer, with frequent hemorrhages, an operable risk, as well as in two cases of gastric cancer.* Besides supplying the lost blood it increases the coagulability of the blood and lessens the probability of further hemorrhage.

When we open the abdomen for duodenal or gastric hemorrhage, what should we do? Gastroenterostomy is the safest operation that is at the same time reasonably sure of being successful. As already stated neither this alone or with any form of unilateral exclusion will absolutely prevent recurrence of hemorrhage. If the patient's condition and the situation of the ulcer permit exclusion may be added. I have made the mistake of attempting too much, planning a v. Eiselsberg exclusion but being compelled to resect by the condition of the stomach rendering the closure of the distal pouch impossible. Many methods have been tried, but they are either less safe or less sure than gastroenterostomy.

In a case of hemorrhage from an ulcer near the cardia, where I feared that gastroenterostomy would not fulfill the requirements, I ligated the afferent vessels by ligatures passed by a curved needle, with an excellent result. Opening the stomach to search for the source of hemorrhage, when there is no apparent ulcer, is seldom successful and is not to be encouraged.

There is no question raised as to the need of operation at the earliest possible moment in acute perforation. As the results are better the earlier the operation, an early diagnosis is most essential. Sudden, very acute, epigastric pain, usually but not always preceded by a history of indigestion, and

*I have also used it in a recent case 9 days after gastroenterostomy, when 2 hemorrhages made the patient very anemic, to enable me to explore. The hemorrhage was found to come from the penetrating ulcer and not from the stoma, through which most of the blood entered the stomach, as the pylorus was very constricted, but not entirely closed by infolding.

soon followed by a board-like rigidity and epigastric tenderness are sufficient for diagnosis. Later the maximum tenderness may shift to the right lower quadrant, and I have operated with the diagnosis of appendicitis, made by the visiting physician. Most acute perforations are on the anterior wall and hence are accessible to operation. If closure by suture in two layers is not feasible a tag of omentum may be employed. Packing alone or around a rubber tube has also given good results in exceptional cases. I always employ drainage through a suprapubic stab wound.

The addition of a gastroenterostomy is a disputed point. According to Paterson² symptoms return in 23 per cent. of those who recover and 11 per cent. die of a second perforation, hemorrhage, or leakage in the suture line. Gastroenterostomy promotes the healing of a perforated ulcer, prevents a subsequent perforation and the recurrence of symptoms. But Paterson goes farther and claims that it diminishes the mortality by making the closure more secure, facilitating peritoneal drainage through early catharsis, and allowing early feeding. Our immediate concern is with the saving of life, hence Paterson's claims, if confirmed, rather than the ultimate result, would be the strongest indication for gastroenterostomy. I fully believe in gastroenterostomy if the patient's condition does not absolutely contraindicate it and especially if the satisfactory closure of the ulcer may result in stenosis.*

Subacute and chronic perforations result in perigastric and subphrenic abscess, which demand accurate diagnosis to indicate the operation suitable to the case.

In conclusion, I wish to emphasize the following:

1. In duodenal and pyloric ulcer gastroenterostomy, with or without pyloric exclusion, gives excellent results.
2. In indurated gastric ulcers, resection or mesogastric resection are far preferable to excision and are to be employed if there is the least suspicion of malignancy, or if it is doubtful whether gastroenterostomy alone will lead to the cure of the ulcer and so protect the patient against the danger of malignant degeneration.
3. Direct transfusion of blood may play an important part in the treatment of gastric hemorrhage.

117 BASE THEORY SURGERY

*An example of the result of the failure to add gastroenterostomy, after closure of a perforation 2 years before, occurred in a case which I recently operated for continued ulcer symptoms and partial pyloric obstruction. The ulcer was still unhealed and active, and the pylorus was slightly stenosed. It was treated by gastroenterostomy and functional pyloric exclusion, by infolding.

INDICATIONS FOR SURGERY OR DEEP ROENTGEN THERAPY FOR MYOMATA AND METROPATHIES.*

BY CHARLES A. PFENDER, M.D.,

WASHINGTON, D. C.

ROENTGENOLOGIST, GALLINGER MEMORIAL HOSPITAL, GEORGETOWN UNIVERSITY HOSPITAL, AND SIRLEY MEMORIAL HOSPITAL.

IT is indeed a privilege to be permitted to present for your wholesome interest the subject of deep Roentgen therapy as applied to myomata and metropathic conditions so frequently encountered in your practice. I invite your attention to the consideration of facts, not fancies, and would bespeak a broad-minded and prayerful discussion, bearing in mind the vital question: Should we do unto our patients as we would like to be done unto? As true healers of the sick and afflicted we should well weigh the evidence from the broad standpoint of a world-wide humanity and practical scientific attainments.

It is indeed fortunate that medical men have been slow to accept new theories and adopt with inherent reluctance methods that had perhaps not been fully proved—and such conservatism is commendable; but when a method has been raised from inexperience and doubtful efficacy to brilliant achievements, in some instances even superior to older and more popular methods, it is well for the alert physician, and the surgeon and gynecologist in particular, to take heed early of these progressive measures and become associated with the modern attainments as a leader and not merely a follower of men.

The wonderful possibilities within the area of deep radiation date back, as you are perhaps aware, to the accidental discovery of the x-ray by Professor Roentgen of Würzburg, Germany, in 1895. The investigations into the mysteries of this new ray soon crystallized into two divisions of practical utility: Diagnosis and Treatment. As a diagnostic factor it stands to-day unchallenged and supreme. It is the best friend of the surgeon in time of need, and although there are some phases still untouched and veiled in mystery, yet its course has been one of constant improvement with but little variation, and has won universal esteem and confidence.

Roentgen therapy has had a harder row to travel. The difficulties encountered on every hand almost overwhelmed the pioneers in radiation, and it seemed that when one handicap was mastered an even more difficult one would arise to take its place. It took many years to surmount the technical difficulties that were encountered in the treatment of merely superficial lesions, and the possibility of fruitful deep radiation was hardly thought of fifteen years ago.

The factors which seemed to baffle the application of Roentgen rays as a successful therapeutic measure resided largely within the domain of the mechanical instrumentarium, and it remained for physicists to solve the problem. The crux of the situation lay in three salients; the energizing medium, the tube, and the filter. The first to be solved was the development of what is commonly spoken of as an interrupterless transformer of high potential, such as can be seen to-day in practically every Roentgen-ray department. The control of its output was only recently perfected. The second problem was clarified by the discovery of the use of substances as filters for the purpose of restrain-

*Read before Georgetown University Medical Society, Dec. 18, 1915.

ing undesirable rays and yet allowing other rays to penetrate. Water, glass, leather, chamois skin, copper, zinc, lead, aluminum, and other materials were tried in many experiments and in varying thicknesses, and out of these, by processes of exclusion, we arrived at the intelligent and effective use of leather and aluminum filters. These range from one to four millimeters in thickness.

The solution of the third and the most difficult problem was effected in a more gradual way. The ordinary Crookes' tube was used by physicists long before Roentgen's discovery, and I here show a facsimile of the tube used by Roentgen when he discovered the ray which he named the *x*-ray. You will observe upon inspection of these drawings that very little progress or change in appearance of the tubes was noted for many years. The men who attempted radiation with the tubes available in those days found it next to impossible to treat effectively any major lesion because the tubes soon got so hot that they failed to work. A long step forward was the development of a water-cooled tube; and with the introduction of this type deep Roentgen therapy was given fresh impetus. But even this tube was far from satisfactory, and limited the Roentgenologist in many ways. It remained for an American physicist, Dr. W. D. Coolidge of Schenectady, N. Y., to perfect a tube that has revolutionized the field of deep Roentgen radiation.

With these details in the armamentarium of the Roentgenologist, perfected as they are to-day, however, results are being achieved that surpass the fondest hopes of the early pioneers in *x*-radiation. Yet we have by no means reached the crest of the therapeutic wave; far greater results must crown our efforts before we can feel that malignant growths may be generally subjugated and destroyed by *x*-radiation. In the therapy of benign tumors and in metropathic conditions, however, results have been universally successful since the improved technique has been properly employed.

In the light of our present knowledge we can safely say that Roentgen therapy deserves consideration in all operable tumors for the reason that in many instances radiation offers an equally good or better prognosis than surgical procedure.

At the present time a rather uniform technique, with slight individual variations of application, is in vogue in the treatment of uterine fibroids. Roentgenologists are agreed in every detail with the one exception of the number and sizes of areas treated at one series and possibly the size of the fee involved. A few employ very large areas, giving a total of only four erythema doses at one series, while others treat from eight to sixty areas at one series and probably collect proportionately. I usually crossfire in six to eight areas at one series, and repeat in three or four weeks. The tube is brought as close to the body as possible, the skin-focus distance usually being about 8 inches, sometimes less. A spark gap of 8 to 10 inches is enforced and from 5 to 8 milliamperes used over each area until an erythema dose is attained, which usually requires from three to six minutes, depending on the milliamperage and the skin-focus distance. I use four millimeters of aluminum and one piece of sole leather to filter out the soft rays, and I insist on protection of the patient by covering head and body with sheet lead or rubber infiltrated with lead. It may not be absolutely necessary to do this, but I am inclined to apply the maxim, "safety first."

X-radiation causes vital changes in the cells. This

is manifested by the arrest of the toxin formation and proliferation of pathological cells and gradual death of these cells which are then absorbed. These cells are more susceptible to radiation than the normal cells in their vicinity, and as a result they can be influenced and destroyed by these rays without injury to normal adjacent cells. In other words, the rays exert a selective action on tumor cells, causing their destruction.

Schultz, Heineke, Martini, Clunet and others have studied the histological changes in the cells of certain tumors that had been radiated and noted first an enlargement of the cells and a distention of the protoplasm and nucleus. The cells then undergo granular degeneration and are absorbed. In place of the tumor there is left a tissue approximately more normal in type, mostly sclerotic connective tissue.

At first roentgenologists and gynecologists did not believe that Roentgen therapy produced atrophy of myomata. This point to-day is generally accepted. Numerous publications report not only a decrease in the tumor but produce evidence to show that the myomata had disappeared entirely. As early as 1902 Deutsch and Morton reported a decrease in the size of tumors they had radiated. Runge demonstrated absolutely positive atrophy in 25 per cent. of cases. Albers-Schönberg noted a decrease in the size of myomata in 45 per cent. of cases, and in 18 per cent. he observed a complete disappearance of the tumor. Siegel found in 36 cases of fibroids that had been treated 9 months previously that the tumor had disappeared entirely in 20, and had been greatly reduced in size in the remainder. Fraenkel observed atrophy of the myomata in 75 per cent. of his cases.

The decrease in the volume of the myoma occurs in one of two ways: (1) Through the ovaries, analogous to shrinking during the climacteric or after surgical removal of the ovaries, or (2) by a direct selective action on the tumor cells.

The latter view met with marked opposition at first, but is now accepted. Schönberg as early as 1910 pointed to this possibility. He observed a shrinking and softening of the tumors in several cases treated in women who were beyond the menopause. One must necessarily attribute this to the direct effect on the myoma cells because in these cases senile atrophy of the ovaries had taken place many years ago. This view was substantiated by others. R. Myer found a decided hypertrophy of the connective tissue, associated by marked disappearance of the muscular elements in very small myomata poor in connective tissue. Some French writers are of the opinion that young myomata react better than old ones. Myomata with rich vascular network undergo atrophy analogous to angiomas. Wetterer believes that the effect on fibroids is caused by hypertrophy and vascular occlusion. Others again believe that very rapidly growing tumors can be caused to shrink more rapidly than those which develop more slowly. Eymer believes, for instance, that the decrease in volume of the fibroids in cases where bleeding still persists is proof that the tumor tissue itself is affected by the radiation. Albers-Schönberg is convinced that the action on the myomata is primarily an ovarian one, but in a notable percentage of cases there undoubtedly is exerted a direct effect on the tumor cells, manifested by atrophy or disappearance of the tumor.

The literature teems with case reports of tumors

of the uterus successfully treated by radiation. Among hundreds of others we note a report by Peyron who observed an interesting case of uterine myoma where the tumor was larger than a child's head and extended from the symphysis to 3 cm. above the umbilicus. This tumor had been growing for 10 years and had so impaired the general condition of the patient that she was completely disabled. Under Roentgen therapy the tumor was reduced in four months to the size of an almond, while the patient's general condition was restored to perfect health.

My own series of cases is not very large, and it may be presumptuous to refer to any personal deductions on the effectiveness of Roentgen therapy in uterine fibroids, but it may prove illuminating, nevertheless, to report one of my first cases by way of illustration:

CASE I.—Miss M., aged 36, suffered greatly from general systemic exhaustion; had large right ovarian cyst removed June 20, 1911. Numerous intramural fibroids were noted in the uterus at the time. These tumors were small, however, and hysterectomy was not done. Patient recuperated very slowly from operation and was convalescent for about nine months before she was able to return to her duties as stenographer in one of the Government departments. In August, 1912, she began to notice a small swelling on left side of abdomen which caused considerable pain and pressure on the bladder. Examination proved this to be a uterine fibroid about the size of a golf ball. Patient dreaded another surgical procedure on account of her delayed recovery from the previous intervention and was referred to me by a friend with the view of obtaining electrical treatments. I advised deep Roentgen therapy to which she consented. Exactly five days after the first series of treatments the patient noted a disappearance of the bladder pain and pressure symptoms. A slight decrease in size of the tumor could be observed when she returned for the second treatment one month later. At the end of the third series of treatments the tumor was no longer palpable, and there has been no recurrence of growth or symptoms to date, three years later. I saw the patient only last week, over three years since radiation, and was told that she had had no return of her former symptoms. This case received radiation only over the site of the tumor and perhaps some of the rays reached the left ovary; nevertheless, there was no disturbance of the menstrual function which is still normal and regular.

Roentgen therapy has also won a firm place in the treatment of metropathic conditions. It is true we must bear in mind the effect that intensive radiation exerts on delicate ovarian follicles, with the likelihood of injury to the ovule; therefore, young women should be advised of this sterilizing action. On the other hand, preclimacteric metropathies are treated with brilliant results, and it may later prove possible to bring about amenorrhea in every case regardless of age.

I should like to report a case which came under my observation over two years ago. The results obtained in this case are not at all unusual; in fact, we expect such results in all cases and usually obtain them after a very short period of radiation.

CASE II.—Mrs. W., white, aged 48, had experienced menstrual irregularity for past eight years. I first saw her about a year before x-ray treatments were given. She gave a history of metrorrhagia with gradually diminishing intervals from thirty days to fifteen days. She presented the clinical picture of extreme anemia and was bedridden most of the time. Rest in bed, ice, ergot, hydrastis, etc., at the menstrual period proved of little value. Surgical interference was declined. On July 19, 1913, deep Roentgen-ray therapy was begun. This was immediately after cessation of bleeding following a menstrual period. The standard water-cooled tubes with 2 millimeters of aluminum as filter were used. The treatments were repeated in three weeks and menstruation had not yet returned at

that time. Twenty-four days after beginning of the x-radiation a scanty flow appeared, lasting for four days. The amount was less than she had experienced at any time since the beginning of her trouble eight years ago. The patient and family appeared skeptical as to results of x-ray treatments in the beginning, but noting the quick result obtained they were encouraged to continue treatments at intervals of a month for three months, after which treatment was stopped. The menstruation ceased entirely after the first treatment and has not recurred. This was over two years ago and the patient is still enjoying perfect health, after a period of invalidism for nearly eight years.

The most convincing statistics at hand today are those reported recently by Gauss, of Freiburg. Whatever else one may think or feel about some of the things that have come from Freiburg the following table merits consideration and study:

RADIATION DOSE AND PERCENTAGE OF CURES IN ROENTGEN THERAPY OF MYOMATA AND METROPATHIES.

Groups	No. of Cases Treated	Cures, per Cent	Improvement, per Cent	Failures, per Cent	Died, per Cent	Recurred, per Cent	Lost Sight of, per Cent
Group I (50-175X)	693	72	13	4	0.5	4	9
Group II (175-500X)	544	82	11	5	0.0	3	2
Group III (500-1500X)	158	95	5	1	0.0	0	0

Group I was treated by thin filters or no filters at all; the results were therefore relatively poor. Group II shows considerable improvement, and this was due to the use of thicker filter allowing more intensive radiation. Group III gave the best results, and in these the hard metal filters were employed.

It is important to note that the material selected in the three groups varied. The first group is composed of selected—that is, favorable—cases, with the exclusion of all cases that showed any indication of difficult cure. In Group II are included cases that had not been permitted to receive treatment in Group I, and Group III includes practically all the cases of myoma and metropathies that came to the clinic. This is an index of the confidence of the leaders of the clinic in this method, a proof that is further amplified by the fact that the number of failures and recurrences diminish in Groups II and III, in spite of the broadening of the indications for treatment. This is partly due, of course, to improved technique.

With such results of radiation before us it is difficult to escape the conclusion that the great majority of myomata and metropathies should not be brought to the operating table. It matters not how elegant the technique of such operations, how good the operative results, one factor will always weigh heavily against the operation and in favor of radiation, namely, that the operation in large unselected series of myomata and metropathies is accomplished by a primary mortality of 3 to 5 per cent.

When the public awakens to the fact that Roentgen therapy in myomata and metropathies is equally as successful and less dangerous than operative procedure it will demand its employment in these cases.

The opponents of deep Roentgen therapy in gynecology, for want of no better argument, raised the point that so many fibroids are found at operation to be sarcomata. They assume that had these patients been radiated they would have invariably died from the ravages of this disease. Let us see on what facts they premise this argument. The masterful compilation by James Ragland Miller

throws an entirely different light on the subject. The following table shows conclusively that in more than 10,000 cases of myomata which came to operation only less than 2 per cent. were sarcoma. In the next table you will observe that in more than 6,000 radical myomectomies the mortality rate was practically 5 per cent.

OCCURRENCE OF SARCOMA.

	Myoma	Sarcoma	Per Cent.
Compiled from 26 operators.	9750	192	1.96
Lewis	1518	22	1.4
Olshausen	6470	77	1.2

RADICAL MYOMECTOMIES.

	No. of Cases	Deaths	Per Cent.
Compiled from 22 operators.	6646	324	4.87
Döderlein Krönig	1982	99	5.00

Not content with the presentation of facts as noted in the foregoing tables, Miller investigated the operative results of sarcoma in 180 cases and found that only 23 or 12.7 per cent. remained free from recurrences 12 months after operation. Roentgen radiation combined with surgery would have saved twice as many or more.

OPERATIVE RESULTS OF SARCOMA.

	No. of Cases	Died	Not Observed More than 12 Months	Free From Recurrence 12 Months After Operation.
Compiled from 13 references and operators.	180	81	76	23, or 12.7%

Miller also states that "since October 10, 1906, all myomata removed by operation in the Freiburg Frauenklinik have been carefully examined in the pathological institute under the control of Professor Aschoff. Up to February 7, 1911, among 249 myoma cases not a single sarcoma was found. Between February 7, 1911, and July 28, 1912, there appeared suddenly 5 sarcomata among 69 cases. It would be wrong to draw any conclusions from either series of cases.

"In the space of time between January 1, 1909, and February 7, 1911, 47 myoma cases were treated entirely by x-rays, between February 7, 1911, and July 28, 1912, 138 myoma cases were rayed. No one of these has up to the present time shown signs of malignancy."

"Among the 318 operated myomata were five sarcomata, i.e. 1.6 per cent. If we reckon the x-ray cases with these, we should get 501 myomata with 5 sarcomata, or 1 per cent. Furthermore, had we as a matter of principle treated every case with x-rays, we should still have rayed only 3 out of the 5 sarcomata. Case 2 was pregnant and Case 5 was previously diagnosed. Again, Case 1 died after operation. She could not have done worse had she been treated with x-rays, the probabilities being in favor of prolongation of life for several months." (*Surgery, Gynecol. & Obst.*, March, 1913.)

Now, as to the indications for deep Roentgen therapy in metrorrhagia at or near the menopause. Radiation is *always* indicated in climacteric and preclimacteric bleeding from the uterus. This should be preceded, if possible, by a microscopic ex-

amination of scrapings from the uterine mucosa in order to exclude a malignant degeneration of the mucosa.

In all cases of fibroids where the patient suffers from marked anemia or myocarditis or from renal disease or from any other disease that would endanger the life of the patient if subjected to surgical measures deep Roentgen therapy should be done. The one exception would be in cases where the size of the myoma caused dangerous pressure symptoms of equal gravity as an operation for possible relief.

In all cases of fibroids where deep Roentgen therapy fails to reduce the tumor or arrest the bleeding the patient should be referred for operation.

The symptoms produced by myomata are usually considerably improved or completely removed by radiation. The hemorrhages are converted to a normal menstrual type. Oligomenorrhea or amenorrhea are attained. The general condition is improved, and the concurrent symptoms are slight.

The percentage of completely cured cases is high. Permanent cures are obtained with certainty in suitable cases. A small number of myomata remain uninfluenced by radiation. Such cases as have been radiated can still be treated surgically if the symptoms justify operation.

Not all myomata are adapted for Roentgen therapy. The contraindications are: (1) Malignancy or a suspicion thereof; (2) large tumors causing severe pressure symptoms; (3) submucous myomata; (4) suppurative or degenerative myomata; (5) cases in which diagnosis of myomata cannot be made with certainty; (6) adnexal complications, such as salpingitis or similar inflammatory processes.

304 RHODE ISLAND AVENUE, N. W.

A UROLOGICAL CASE THAT TEACHES THE NECESSITY OF SCIENCE, SYSTEM, AND COMMON SENSE.*

By G. S. PETERKIN, M.D., F.A.C.S.,
SEATTLE, WASH.

THE rules of the Swedish Hospital Clinical Society require that a complete history of an authentic case be presented, but not in a manner that will disclose the diagnosis, for the diagnosis is to be made by the members of the society. On invitation the following urological case was presented. This case was selected because a common, ordinary, every day case, yet an example of a class in which the greatest percentage of mistakes in diagnosis is made, due, no doubt, to the simplicity of the symptoms complained of.

THE CLINICAL CASE.—M-409, male, aged 19, referred by Dr. G. Ormond, Cumberland, Wash. First visited office on March 24, 1915. Complaint: Urethral discharge; exposure to infection July 19, 1914; discharge commenced three days after exposure. Diagnosis: Chronic gonorrhea. Previous treatment: Local injections and internal medication to within three weeks of consultation. At no time was there a discharge sufficient to soil clothing. Subjective symptoms: Sensation of burning on urination and increased frequency; frequency every four to five hours instead of every six. Discharge more profuse each morning, and could be obtained by stripping during the day. No microscopic examination made.

Clinical symptoms: Complement fixation tests for syphilis and gonorrhea negative. Specimen of urine voided at night in sterile bottle was normal in appearance and color; reaction acid, S. G. 1.030, no albumin,

*Read before the Swedish Hospital Clinical Society, Seattle, Washington, December 7, 1915.

no sugar, no casts. Morning specimen, patient retaining urine eight hours; this urine centrifuged and examined for bacteria. None present. Patient instructed to hold his urine for four hours, and following examination made: Two slides of anterior urethra taken. Few pus cells and staphylococci.

Anterior urethra then irrigated with sterile salt solution to the compressor urethrae under gentle hydrostatic pressure in order to wash out thoroughly any pathologic material hidden between the folds of the collapsed anterior urethra, irrigating fluid caught in sterile basin and placed in sterile ignition tubes (Fig. 1), marked 1, centrifuged, examined microscopically; findings negative. Patient then instructed to void urine retained in the bladder four hours, in sterile ignition tubes 2, 3, and 4. These specimens were centrifuged with the following results: Tube 2 showed condition of posterior urethra, numerous leukocytes, considerable mucus, no bacteria. Tube 3 showed extent of inflammation of posterior urethra, negative. Tube 4 showed condition of bladder, negative.

The patient's bladder was then filled under hydrostatic pressure with sterile salt solution to its fullest capacity. Fifty c.c. voided in Tube 5, or control tube. This was centrifuged and the findings were negative. Therefore I was able to state that the whole urethral canal was now free from infection, since cleansed by anterior irrigation, urination, and twice by sterile salt solution used to fill bladder. The urethra having been thus cleansed and rendered sterile, the prostate and seminal vesicles were massaged, some of the expressed contents placed on warm slide, examined microscopically; they showed spermatozoa normal in size, shape, number, and activity. Therefore, the testicles and seminal vesicles were normal. The sterile salt solution retained in the bladder was now voided, washing out thoroughly from the urethra all contents expressed by massage from the prostate and seminal vesicles. This specimen centrifuged and examined. Findings negative.

Clinical examination of external genitals showed no abnormality. Palpation of prostate with bladder full, bladder empty, and sound in urethra, showed normal prostate. Urethroscopic examination, cystoscopic examination, bougie-à-boule and sound, negative. Yet there is no question, even though all the clinical and

Diagnosis.—The diagnosis is a guilty conscience combined with a crude and imperfect knowledge of the physiology of the sexual organs. Admitting exposure to infection and providing no pathologic condition exists, there are six explanations, any one

FIG. 2.—Wall charts, open and closed. The economy of time effected by the above arrangement is evident.

FIG. 1.—Battery of ignition tubes.

laboratory reports showed negative results, that the urethral discharge complained of by the patient did and does exist. It was sufficiently apparent to indicate treatment to a physician.

Question: What are the diagnosis and treatment?

of which or any combination of two or more of which, can cause a non-bacterial urethral discharge, innocent in its innocuousness, yet too often credited with the militancy of la Goutte Militaire. These are: (1) Erection and collapsing of organ. (2) Continence, with discharge of overflow from prostate and seminal vesicles. (3) Frequent stripping of normal urethra. (4) Local treatment, no infection existing. (5) Concentrated urine, or urine containing excess of phosphates, uric acid, etc. (6) Meatotomy, producing a non-bacterial catarrhal mucous membrane. In this instance it was a combination of 1 and 3.

Treatment.—The treatment is psychological. Psychological treatment, to be efficient, must be scientific. In other words, the physician's knowledge must be such that he is able to explain on a scientific basis existing phenomena, and above all, to impart this information in a comprehensive manner to the patient, irrespective of his social or mental status. Permission granted, I will here demonstrate the truly practical side of this case, the method of administering this psychological potion scientifically. Before doing this, however, it is desirable to make a few general introductory statements, the bearing of which, if not apparent now, will be sufficiently apparent before I finish.

It is true that 99 per cent. of all doctors practise medicine for a livelihood, therefore as a business; that the business man who can display and demonstrate the value of his wares to the greatest pos-

sible advantage, not only succeeds, but supersedes the man who does not. This is true in medicine, for the physician who can display his knowledge, who writes successfully or talks successfully, or both, succeeds and supersedes the man who does

FIG. 2.—Cross-section of the male urogenital organs

not. Yet in this economic era, all businesses and professions, except that of medicine, recognize this fact to the extent not only of devising but continually improving means and methods whereby they can inculcate this principle of action in the individual.

It is characteristic of mortal men that even the best may err, fail. This element, the element of chance, always exists, in every pursuit of life, and medicine is no exception. The battle cry of today, the battle cry of art, science and commerce, is *efficiency*. *Efficiency* signifies here in the profession of medicine, as it does in any walk of life, the reduction to the minimum of this element of chance by thoroughness in detail, using all methods of examination and then checking one method by the other, and finally, as a business man would say, balancing the account. The account balanced, outline the principle of action, then do not hesitate, but go full steam ahead. In other words, possessing efficiency, the time has arrived that medical men should show the public that the scientific physician sells scientific medicine and gives full value received, depends, like the modern salesman, on the quality and the character of the goods (scientific knowledge) he sells, not like the old time drummer, on the antiquated and unsystematized methods of personalities, good fellowship, storytelling, gossip, treating, pretension of friendship, etc., which the medical man of today still employs.

We now come to the gist of the subject—the real object of presenting the case, which is to illustrate the art and method of selling scientific knowledge and the necessity of so doing. In this instance, by this method only—the employment of science, system, and common sense—can we administer this psychological potion scientifically.

First and foremost, classify your patient. Here

we have the patient's character, mentality, and environment—a lusty farmer lad of nineteen. Therefore, we must use illustrations and word pictures that will give him a definite mental conception of existing conditions—conceptions so clear that there will be no possibility of doubt in his mind as to the accuracy of the information imparted.

In the private office are wall charts (Fig. 2), which when not in use are kept closed. These charts are diagrammatic anatomical drawings, used to illustrate points made in explaining to the patient his condition. Fig. 3 is the first of the series and is enlarged so as to be distinct.

After the examination, standing in the private office before the open wall charts, the following explanation is given the patient:

Doctor (pointing to corresponding number or anatomical part as explanation progresses): "This drawing (Fig. 3) shows the urinary and sexual system in a man. The urine is manufactured in the kidneys (1), goes down through this canal (2) to the bladder (4), the reservoir where it is stored. When you pass your water, it comes out of the bladder (4) into this canal (5), then goes through it out of the meatus (24) or mouth of the penis. The semen, or the fluid in the man which makes a child, is manufactured here in the testicles (7), comes up through this canal (9), to the reservoirs (10) where it is stored until used. When used it comes out through the small canal (11) into the same canal, the urethra (5), through which the urine is passed, and then goes out through the mouth of the penis, or meatus (24). (13) is the shutoff muscle. This is the muscle which you can open or close when you want to pass your water; therefore, it is under the control of your mind. It divides the canal (5) into a front and back part. Back of this muscle (13), between it and the mouth of the bladder, is a gland the size of a horse-chestnut, called the prostate (12). This gland is made up of fifteen or twenty other glands like bunches of grapes (20), all of which open into the canal (5) and discharge a fluid which passes through the same canal through which the urine and semen pass.

"You see how all these parts connect with one another. Now the germ, or bacteria, which causes gonorrhea, or clap, looks like a coffee bean (illustrated). To look the size of even the head of a pin under the microscope (a magnifying glass) it has to be magnified or enlarged twelve hundred times. To know how small the germ is, try to think of something twelve hundred times smaller than the head of a pin. You can't do it! Yet, because this bug is so tiny, and because the sexual and urinary tracts are connected, this germ which causes gonorrhea may start at the meatus (24), enter any of the glands of the urethra (5), pass back of the shut-off muscle (13), enter any one or all of the different glands of the prostate glands (12), pass into the bladder (4), and up to the kidney (1). Or it may pass behind the shut-off muscle (13), enter the canal (11),

FIG. 4.—Cross-section of the urethra.

the opening to the reservoir for storing semen, and so reach this reservoir, (10), from there it may pass down through the canal (9), to the testicles (7), and then the testicles swell. Since this germ is so small and the sexual and urinary tracts are so connected, you can

see an examination is no good unless it prevents the overlooking anything so small as this germ in a field so great as these connected tracts.

"Now, this is the way we go over this whole tract so that we are dead sure we do not miss any of the germs, if they are present: First we took some secretion or fluid from the front part of this canal (5), put it on slides, or little pieces of glass, and put it under the microscope and examined it to see if the germs were there. If we cut the penis across, we see that the inside of it is thrown into folds (Fig. 4), for anything that expands and collapses must be thrown into folds when collapsed. Therefore, we next wash out the front part of the canal (5) from the meatus (24) to the shut-off muscle (13) with a sterile solution (absolutely clean water), so as to stretch out every fold and get any germs that might be hidden in these folds. This fluid or solution was caught in a sterile, or perfectly clean, basin, centrifuged and examined for germs. You don't know what centrifuged means, do you? Well, a centrifuge works like a milk separator—you put the fluid in and whirl it around very rapidly and the solid part goes to the bottom. This bottom part we examined, for it will show the germs if there are any present.

"Then you passed your water into three tubes. The first urine passed washed out the back part of this canal (5) between the mouth of the bladder and the shut-off muscle (13), just as water running through a slough will wash out dirt and sticks, the second tube would wash out any bugs that were left after the first urine had passed over this part, and the last tube, which is filled with the very last drops of urine in the bladder (4), would show if there was trouble in the bladder. These tubes were centrifuged also, and examined. Then we filled your bladder with a sterile, or perfectly clean, solution, and you passed out fifty c.c.—remember, up to the mark on Tube 5? This water coming out cleansed the entire canal again. You see this water passes over this canal (5) twice, once when we put it in, and once when you passed part of it out. So if this solution in Tube 5 is clean, contains no bugs, we are absolutely sure that the canal (5) is perfectly clean.

"Knowing the canal (5) is clean, then I put my finger in the rectum (22) and massaged the prostate (12), and the seminal vesicles (10), pressing out any fluid or secretion in them into this canal (5), the urethra. Some of this fluid showed at the meatus or mouth of the penis (24), and I put it on two warm glass slides and examined it under the microscope. You see the fluid that comes from the seminal vesicles contains the spermatozoa, or male seed (illustrated). These spermatozoa or seed are alive and have motion, moving like a tadpole. By their appearance, if they are alive and are not misshaped, we can tell the condition of the seminal vesicles (10) and the testicles (7), for if the seed or spermatozoa are all right, the testicles, that manufacture the spermatozoa, must be all right. Then you voided the rest of the fluid in the bladder and this washed out every bit of fluid that we had pressed out from the glands (12 and 10), so that none will be missed. This was centrifuged and examined.

"Now, all these fluids, the first used to wash out the front part, the three tubes of urine, and the two tubes of solution which we put into the bladder, were centrifuged and examined and no germs found in any of them. No germs were found on the slides we took, either. Yet to be doubly sure, we took the blood and examined it to see if gonorrhea was present, but we found no sign of the disease.

"In addition to all this, you were examined by the urethroscope, an instrument with an electric light with which one can see the urethra or canal (5), and by the cystoscope, another instrument with electric lights, with which you can examine the bladder (4). Therefore, if the microscopic examination showed nothing, and we can see nothing, feel nothing, there must be no disease, and there is none. So the question comes up, since you knew there is no disease but that you have the discharge, what makes this discharge?

"The cause of it is as follows: If I turn my lip down, you can see many little drops of water come out from the lining of the lip. These drops of water are saliva or mucus, which comes from tiny glands, so tiny you cannot see them, the purpose of which is to lubricate, or oil the lining of the mouth so that we can talk and eat easily. The penis, you know, is an organ that gets larger and smaller, its lining membrane to stretch must be oiled or lubricated or it will crack, as the lips do

when dry and chapped. Now all along the canal (5), there are just as many of these tiny glands as there are in the mouth. You wake up every morning with an erection, don't you? The penis, when erect, hard, measures about six and one-half inches, and when collapsed, not hard, measures only three and one-half inches. When it is erect, Nature naturally thinks that sexual intercourse is going to take place, and therefore lubricates or oils the whole canal (5) with moisture from these glands, so that the fluid, or semen, which is to pass out will slip easily along the canal, for upon the force with which the semen leaves the canal depends the power to impregnate the female, that is, to shoot it into the womb and make the woman have a child. Now, when this act (going with a woman) does not take place, what happens? The organ goes down from six inches to three inches, and all this lubricating fluid is squeezed together. The penis now hangs down and naturally, following the law of gravity, the mucus, or oil, goes toward the mouth of the penis, and very often overflows the mouth (24). This is the discharge you see every morning. This discharge is clear and is present only in the morning, or during the day if you strip the organ, and by so doing squeeze this normal or natural secretion, which is always present along the canal (5), toward the meatus (24) and make a drop. This secretion or discharge is perfectly normal, and you would not see it unless you stripped the penis, and the more often you do this the more secretion you will get, since you irritate the little glands by rubbing them together, and nature, to relieve this irritation, makes more fluid for lubrication, just as the lining of the mouth makes more saliva when you put something hot in your mouth and irritate it. So all you have to do is not to squeeze the penis, go home and forget about the disease, because you haven't it."

Incidentally, the mother of this boy brought the patient to the office. She had spent considerable money in trying to have him cured and was much distressed in mind, having heard of the horrors, dangers, and damnations of venereal diseases, as depicted by the theoretical moralist who would reform through fear. She was not in the office when the explanation was made to the boy. Therefore the following note was penned, to insure instructions being carried out and to provide against further worry on her part:

"My dear Mrs. ———: After a thorough examination of that boy of yours, I find, as I should have liked to explain to you in detail, that there is nothing, absolutely nothing, the matter with him. The only thing he needs is plenty of hard work—put him at it. Then he will forget about his infirmities, which are only imaginary."

1102-1112 COBB BUILDING.

PULMONARY TUBERCULOSIS AND BODY WEIGHT.

By ISIDOR N. KAHN, M.D.,

NEW YORK.

ADJUNCT ATTENDING PHYSICIAN BRONX HOSPITAL; CHIEF OF CLINIC GOUVERNEUR HOSPITAL.

THE lay conception of one suffering from pulmonary tuberculosis is that of a person who is rapidly losing weight. To this idea the popular term "consumption" is due. The physician's mind, too, often harbors this belief. In his premedical career he entertained the lay idea of the disease, and he often subconsciously continues sharing it, despite the fact that he may have seen numerous instances of patients under his treatment for the disease who either have not lost materially or have even gained weight.

The present report is based on the observation of over 200 cases treated during the year 1912 in the tuberculosis clinic of Gouverneur Hospital. The cases comprise tuberculous patients in all stages of the disease. No attempt has been made to select

cases free from complications. The great majority of the patients are Hebrews. Both sexes are considered. Children under fifteen years of age are not included. The patients were under the care of the clinic for a time varying from three years to a few months or even less.

The fact should be borne in mind that the majority of the patients treated at the clinic are very poor. Many subsist wholly, others partly, by the support of charity organizations. Many rely on the clinic for their only extra source of nourishment—a bottle of milk daily. The few who support themselves often are engaged in work requiring great muscular exertion. None of the patients cited in these tables that follow have had any exceptional treatment outside of the ordinary routine care of the clinic.

It is of interest that at the latest Congress on Tuberculosis held in Washington, D. C., nothing was said concerning the loss of weight in tuberculous patients. Prof. Th. Sommerfeld¹ gives a description of the work and results of the Berlin homes for tuberculous patients for the four years from 1903 to 1907. His report is based on a total of 10,245 cases, in all stages of tuberculosis, with and without complications. He divided his patients into nine groups, as follows:

- 1. Patients suffering from pleurisy, without proof that tuberculosis is present or that the pleurisy is of tuberculous origin.
- 2. Patients with suspected catarrhal condition of the apex of a lung without tubercle bacilli in the sputum, and even without expectoration.
- 3. Positive cases of slight extent, without complications and free from fever.
- 4. Positive cases without fever, and without complications, of such extent that work had to be restricted.
- 5. Positive cases without complications, and mostly free from fever, of such extent that work had to be permanently restricted.
- 6. Positive cases, with fever and without complications.
- 7. Positive cases, mostly free from fever, complicated by disease of the larynx, or of the intestines, or of both.
- 8. Positive cases, with fever, complicated by disease of the larynx, or intestines, or both.
- 9. Patients with chronic bronchial catarrh, emphysema and asthma.

"It is a fact," observes Prof. Sommerfeld, "that even among advanced tuberculous cases considerable increase in weight and notable improvement are obtained." The average increase in weight varied in the different groups between 5.97 kg. and 1.5 kg., and only in groups No. 6 and No. 8 did the number of patients discharged without improvement exceed the number improved. No special treatment is used in the Berlin sanatoria, the general treatment consisting mainly of fresh air and good nourishment.

Our investigations permit the same conclusions regarding the weight of our tuberculous patients. Not only do the patients gain weight during the period of treatment at the clinic, but in a great number of cases the weight of the patient exceeds the normal or standard weight of an individual of the same age.

What is the normal weight of an individual? There is no exact standard. If we compare the various tables that are in general use we find a certain amount of variation. According to Mac-

Glogan² the normal weight of an individual in pounds is the cube of his height in inches divided by 2000. Thus a person 5 feet 6 inches tall should weigh between 143 and 144 lb. Dr. Green³ gives the weight for that height as 152 lb. The Metropolitan Life Insurance Company's table differs from both. It is customary, therefore, to allow a variation of 10 per cent. above and below the standard, and yet consider the individual as having a normal weight.

I have arbitrarily divided my cases into three groups. Group 1 comprises the cases between the ages of 15 and 30. Group 2 includes all patients between 30 and 45 years of age. In group 3 are all cases over 45 years of age. Male and female patients are considered separately. Each group is further classified into the stages of the disease in which the cases happen to be.

In Table No. 1 (males, first stage, ages 15 to 30), the total weight of the patients is 4,854.75 lb., and the total standard weight is 4,984 lb. The total deficit is 130.25 lb.

TABLE I. MALES, FIRST STAGE, AGES 15 TO 30.

5 26	128 ¹ ₄	141
	4,854 ³ ₄	4,984

In table 2 (males, first stage, ages 30-45), the total weight of the patients is 1,670.75 lb. Their total standard weight is 1,709 lb., giving a total loss of only 38.25 lb.

TABLE II. MALES, FIRST STAGE, AGES 30 TO 45.

	2,127	2,130

A considerable loss of weight is observed in all ages in the third stage of the disease. The total present weight of the seven male patients in this stage is 844.25 lb., and the total standard weight is 1,012 lb. There is therefore an average loss of 24 lb. This should naturally be expected in this stage.

TABLE VII—MALES, THIRD STAGE, AGE 15 TO 30

5 6½	147	147
5 2¾	126	128
	844¼ Total	1,012 Total

No loss of weight is found in females of all ages in the first stage. Indeed, some gain is observed. Pregnancies and the normal tendency of women to obesity may explain the total gain. The same may be said of women in the second stage of the disease. In table 8 (females, first stage, ages 15 to 30), the total present weight is 2,269.5 lb. and the total normal weight is 2,255 lb., a gain of 14.5 lb.

TABLE VIII—FEMALES, FIRST STAGE, AGES 15 TO 30

5 0½	111	116
5 4	121½	129
5 3	119½	126
4 11¼	112½	112
4 10	122½	108
4 10¾	107¾	110
5 3	107¾	126
5 4	142¾	129
5 1¾	132½	118
	2,739	2,570

There are but six cases in table 12 (females, second stage, ages 45 and over). These are too few to warrant any conclusions. The total present weight of these six cases is 672½ lb. The total normal weight is 630 lb. So that even here there is a gain of 42½ lb.

TABLE XII—FEMALES, SECOND STAGE, AGES 45 AND OVER

Height Ft. In.	Present Weight Lbs.	Normal Weight Lbs.
5 1	118	118
5 1	150	118
5 1	126	118
5 1½	153½	131
5 6	125	115
	672½	630

As was previously observed, a considerable loss of weight is evident in the third stage of the disease. This is, however, to be expected.

The total present weight of the nine patients in this stage is 1,053½ lb., and the total normal weight is 1,115 lb. The total loss is 61½ lb.

Life-Insurance Losses.—It is estimated that the losses of the British life insurance companies during the first thirteen months of the war exceeded £5,500,000, or \$27,500,000.

FISTULA OF THE RECTUM.

BY CHARLES J. DRUECK, M.D.,
CHICAGO

A FISTULA is a nongranulating sinus within the rectum or about the anus, with one or more openings. This condition is sometimes called fistula in ano, a term which is incorrect and misleading and should be discouraged, as other tissues are always involved and the anus is not always included.

The sinuses nearly always result from abscess in the perirectal or ischiorectal tissues which has opened into the rectum or on the skin surface near the anus. When the abscess develops in the ischio-rectal fossa, it burrows outside or above the sphincter; the levator ani muscle forms its upper limit, and the abscess extends along the lower surface of that muscle into the rectum, usually at the upper level of the sphincter. The resulting sinuses are large and often branched or multiple, and their external openings may be quite a distance from the anus. The whole perineum and buttock may be indurated and hard; or if the abscess has emptied and refilled several times, the parts become honey-combed with a great many fistulae which communicate with one another, or with a common abscess. Some part of the labyrinth is always forming an abscess, and causing intense pain. As a result, the sufferer usually becomes an opium wreck. Kelsey reports between twenty and thirty sinuses in one of these cases. The sinuses thus formed do not heal spontaneously because of the retention of septic excretions and feces in the sinus, and also, on account of the dependent position of the veins when the patient is sitting or standing, which causes a sluggish return circulation, the parts being constantly disturbed during defecation or any movements of the pelvis or legs. The small exit of the fistula helps to retain infection, except in the tubercular fistula, where the opening is usually large enough, but the caseous degeneration of the abscess wall promotes a fistula.

The abscess may form anywhere about the rectum, but is found most frequently in the following locations: (1) Beneath the skin near the anus. (2) Between the mucous and muscular coats of the rectum. (3) Between the rectum and the levator ani muscle. (4) In the ischio-rectal fossa.

Abscesses of the first location are the most common, and a resulting fistula is just beneath the skin and does not involve the sphincter. The internal opening is in the mucous membrane and within the grasp of the external sphincter.

Fistula are classed as. (1) Complete: (a) ordinary; (b) external; (c) internal. (2) Incomplete or blind: (a) external; (b) internal. (3) Horseshoe. (4) Rectovaginal. (5) Rectovesical.

The ordinary complete fistula is a sinus with an internal opening into the rectum and one or more openings on the skin. This is the most common type of fistula, and hence its name. An external complete fistula is one with both of its openings on the skin and not communicating with the rectum, while an internal complete is one with both openings within the rectum and not involving the skin. Not every fistula communicates with the rectum, although the great majority of them do.

An incomplete or blind external fistula is one which begins in the perirectal or ischio-rectal structures and opens upon the skin but does not extend into the rectum. An incomplete or blind internal fistula has an opening into the rectum and a sinus

extending into the perirectal tissues, but has no other opening into the rectum or upon the skin. It differs from the complete variety in that there is a broad undermining of the mucous membrane instead of narrow channels. The internal opening is situated often at the base of an ulcer or hidden in the folds of mucous membrane.

The horseshoe fistula is nearly always an old case, and takes its name from its fancied resemblance to a horseshoe in shape. In this variety the original openings have become blocked, and the retained pus has burrowed in a new direction and found an outlet. Thus a typical horseshoe fistula has one opening within the rectum and one or more external openings on either side of the anus. The pus burrows around the rectum in the loose areolar tissue and forms a new opening on the opposite side of the anus from the first. In burrowing the pus generally passes posterior to the anus, and very often the internal opening is found in the median line posteriorly. There are many deviations from this typical description, as a horseshoe fistula may have only one external opening, and yet the pus may have burrowed all around the rectum and the resulting fistula be either complete or incomplete in form.

Rectovaginal fistula are of two kinds: First, those high in the vagina, and, second, those in the lower part. On the whole, they are uncommon. If the opening is small, there is little escape of feces so long as the stool is formed; but one of the most common and annoying symptoms is the escape of intestinal gas which produces a bubbling or hissing noise. The patient has, of course, no control over the escaping gas, and the odor finally forces her to avoid society and to stay at home, until she becomes melancholy from brooding over her trouble. A fistula in the upper part of the vagina is usually due to cancer of the cervix, which has generally progressed so far that curative treatment is out of the question. In the lower part of the vagina and at the vulva, fistula often results from imperfect union in repairing a torn perineum or from the sloughing of the septum after tedious parturition. Enterovaginal fistula or openings of the small intestine into the vagina, are traumatic openings produced during an operation, or else either congenital or artificial vaginal ani. Rectovesical fistulae, like rectovaginal, are the result of either traumatism or malignant disease.

Fistula about the anus is a very old disease, being described by Celsus and Hippocrates, whose etiology holds good to-day. Very few cases are seen early in their course by the surgeon, as the sufferer first tries all the domestic remedies, because of the old superstition that a fistula is the vent of the system for certain poisonous humors, which are retained if the fistula is healed, and produce by their retention some other malady, of which consumption holds first rank.

Symptoms.—The first symptom which attracts the patient's attention is the local abscess which has the symptoms of any collection of pus, namely, redness, swelling, pain, and fever. The abscess ruptures and discharges its contents, relieving the local distention; the tissues are soft and tend to retract and contract, leaving only sufficient opening to permit the exit of subsequent discharges. The excretions of a recent abscess are thick, abundant and constant, but as the lining membranes grow old and are covered with lardaceous granulations, the discharges become thin, watery, and lessened in

amount. After the abscess has emptied itself, the patient suffers no discomfort except the purulent discharge, which is always fetid in character and sometimes contains gas and feces, making it difficult to keep the parts clean. As the retained pus burrows, forming new abscesses and sinuses, the discharge gradually increases. When the discharge from a given sinus is small in amount and irregular in its outflow, the opening tends to become occluded and retention occurs; thus a new abscess is produced which ruptures through the old sinus or forms a new outlet. In this way two or more fistulae often connect with a common abscess. In any case, if the discharge ceases or becomes irregular, always suspect new abscesses. The incomplete internal fistulae are the most painful, because the retained pus causes pressure during defecation. Such a fistula cannot be diagnosed until a digital examination is made and the finger when withdrawn is covered with pus and blood; the feces also when formed are streaked with pus and blood. Constipation is induced from fear of pain during defecation, and the sufferer goes on in this condition for years before he seeks surgical relief.

Examination.—Much valuable information as to the character of the fistula and its extent is learned from the patient's description. If a slight abscess, recently ruptured and having a free discharge of a small amount of pus is found, a small fistula with openings near the external sphincter is indicated. The position of the patient for examination is largely a matter of choice. The lithotomy position is more advantageous where the trouble is at the anus or not too far within. The Sims position, the patient resting on the affected side, is preferred by many, especially when making a specular examination. When the trouble is high up within the rectum, the knee-chest position is better. No one position suits all cases, and even during the examination of a given case it may be of considerable advantage to change the position, because the entire field must be explored. Even if one fistula is found, a thorough search must be made for others or for other rectal troubles. With such an examination, the diagnosis is not difficult except in internal, incomplete, or in the horseshoe variety. Separate the buttocks by grasping the glutei on either side with one hand, the fingers reaching toward the anus, when by gentle traction the external fistulous opening, if near the anus, will be seen in a little depression or in the center of a mass of granulations in the radiating folds of the anus. The external opening may be, however, quite a distance from the anus, even out on the thighs or legs, and be so small as to escape a cursory examination unless a drop of pus be pressed out during the manipulation. It may be so small as to admit only a fine probe, except in tubercular fistula when it is usually ragged or appears as though in the base of an ulcer. By palpating about the anus, the tracts may be detected subcutaneously by their hardness, and by a finger within the rectum pressing toward the induration a drop of pus will usually exude from the external opening. The tract is sometimes direct from one opening to another, but there is not necessarily a sinus, the abscess may open directly on the surface. In a recent, straight fistula the external opening is large. Sometimes the tract is very circuitous, and the pus may burrow under the gluteal muscles and open in the groin, or on the thigh even as low as the popliteal space. Sir Astley Cooper mentions an autopsy where a fistula opened into the groin, but

he traced it back along the course of the spermatic cord and found it ended in apparently an ordinary fistula in the rectum.

The internal opening is frequently just above the external sphincter, and is found as an indurated spot or a raised mass or else as an ulcer with rough edges. All ulcerated and inflamed spots must be carefully examined, because they often contain the internal opening of a complete fistula or the opening of an internal incomplete.

In case the internal opening is not found, it may be located by injecting milk or some colored fluid through the external opening. The anus being dilated enough for inspection, the fluid will be seen as it comes through the internal opening into the rectum. Injecting hydrogen peroxide for diagnosis has been preferred because the gaseous disintegration dilates all parts of the sinus and bubbles through all the internal openings if more than one are present, but there is also the danger of driving infective material into new and healthy tissue. The short cylindrical speculum is always particularly serviceable in these cases. The internal opening is not always the upper limit of the fistula, but the mucous membrane may be undermined for several inches above the opening.

A word about probing a fistula: Probing at times other than when operating is objectionable and dangerous, because it is painful and may produce new channels, and, besides, affords no information but what is gained from careful inspection and palpation. If the probe is forced out of the sinus and into the tissues, it may mislead the examiner as to the condition of the old fistula, besides carrying infection into new fields and thus forming new sinuses. I never probe a fistula until I am ready to operate, nor do I hunt unnecessarily for the internal opening. It matters little whether you find the internal opening or not before the operation, for when you operate you do.

Spasmodic contractures occur during examination if the patient is awake, which make the examination more painful and dangerous, but when the patient is anesthetized and quiet you have no trouble in tracing out any or all sinuses. When probes are used a large variety are essential, from a fine silver probe to a large, soft, uterine sound. The probe must be introduced carefully and without force until it has gone as far as it will, then with the index finger of the left hand within the rectum, one may find the probe projecting through the internal opening, or, in some instances, covered only with the mucous membrane, or, again, it may have passed away from the rectum and cannot be felt at all.

Lardaceous granulations, the result of chronic inflammation, line the tract of the fistula and contain many new formed blood vessels. The granulations prevent healing of the sinus by keeping the walls apart. A recent fistula is, however, sometimes lined with healthy granulations which form new tissue, and such a fistula may heal spontaneously.

Blind internal fistulæ are the most difficult to diagnose and are found only after a careful examination of the interior of the rectum. Any case presenting persistent uneasiness within the rectum and showing the presence of pus in the stool, unless otherwise explained should be thoroughly examined. The following case is cited to show how misleading the apparent findings of a cursory examination may be:

Mr. S. S. W. passed through a mild attack of typhoid fever and at the end of the third week developed a perirectal abscess which was lanced and which promptly healed except a small sinus. From a pinhole opening of this, exuded a discharge imperceptible in amount, but sufficient to keep the parts moist and fetid. A digital examination of the rectum some months later revealed a small amount of induration above the external sphincter, but no distinct cordlike sensation that would signify a sinus. The director was introduced and brought out at the margin of the anus, and the tissues divided along its full length, thus exposing a suppurating surface irregularly circular in outline, about one and one-half inches in diameter. All the edges and pyogenic surface of this ulcer were removed and the openings of two deeper sinuses were brought to view. The first tract led almost to the base of the urethra and important structures had to be separated to lay it open; the second penetrated the rectum just above the sphincter. This latter opening was closed with chromicized catgut sutures after the method of treating rectovaginal fistulæ, and with the connective tissues sutured over the first stitches to give additional support. The sinus leading toward the deep perineum was packed wide open and allowed to granulate from its base. It is important to mention at this time that the finger within the rectum detected nothing that would suggest deep sinuses, but nevertheless, two very important diverticula existed. Inspection of the case gives the impression that this is a simple external, complete fistula which would heal kindly if divided on the director. However, such an operation would have been worse than useless, because only the outer part of the sinus would have healed over, to reform again in a few weeks. The stereotyped operation as set down in the text books, or treating the sinus by astringent injections would have been a signal failure.

This case is related in detail and the illustration given to show that each case must be treated upon its own conditions. Frequently narrow branched tracts lead off into the deep tissues and perhaps encroach upon vital organs.

STUDY OF THE BLOOD WITH A NEW STAIN.

PRELIMINARY REPORT.

By B. LEMCHEN, M.D.,

CHICAGO.

I TAKE it for granted that cells and tissues of similar composition will react alike to stains, as it is generally admitted that staining is a chemical reaction.

The stain I have made for blood smears consists of a saturated solution of benzidine in absolute alcohol. After making the blood smears on slides I put this solution on it for about half a minute. This fixes the blood on the slide and also impregnates the stain. Then I add hydrogen peroxide. After about half a minute I wash the slide in water and dry it in filter paper.

I have found on examining the smears that the red cells are stained blue. Nucleated red cells, the cells together with the nucleus, are also stained blue. White cells do not take the stain. The blood platelets do not stain. I have also found, if I let the blood smears stand for a couple of hours so that fibrin will form, the fibrin also stains blue. The conclusions to be drawn from this are that the red cells and the white cells have different origin, that the platelets have not their origin in the nucleus of the red cells as has been thought for some time, and also that the fibrin apparently has the same composition as the red cells. Whether or not the breaking down of the red cells forms a substance necessary for the coagulation of the blood I am unable at present to say, but on the same rea-

soning, in all probability, this process is originated by the red cells. This might explain the great destruction of red cells in pernicious anemia, as it has been thought for some time that pernicious anemia is probably some form of hemophilia. If my conclusion that the coagulation of the blood has its origin, in part at least, in the red blood cells is correct, it will account for some forms of hemophilia producing extreme pernicious anemia. With this same reasoning it might be assumed that the agglutinins in typhoid might have their origin in the red blood cells. This also might account for the marked anemia we get in typhoid, and also for the increase in size of the spleen and the great activity of the lymph and hemolymph glands, as it is known that one of the functions of the spleen and of the hemolymph glands is to destroy red blood cells, and it might be that these glands destroy a number of red cells, which liberate the substance necessary for the production of agglutinins. The substance, whatever it might be, is carried to the liver and there apparently the molecules are rearranged for specific agglutinins. Further study in this line is necessary to come to a definite conclusion.

CHICAGO STATE HOSPITAL, ILLINOIS, ILL.

Medicolegal Notes.

Malpractice—Expert Evidence as to Treatment—Patient's Duty to Minimize Damage.—A workman in a logging camp was severely injured by a log rolling on his foot. His hurts consisted of a dislocation of one of the cuneiform bones and two cuts in the top of the foot. In an action for malpractice in its treatment, it appeared that the defendant had the contract to treat the men under the hospital fee system. Infection followed the wound, and the plaintiff was confined to his bed for from six weeks to two months. After leaving the hospital he called on the defendant two or three times seeking relief from pain. The defendant advised him to get some light work, and he would probably have a good foot. The dislocated cuneiform bone—described by one of the medical witnesses as the keystone of the arch of the foot—was pressed downward and forward so that when the plaintiff walked the weight of his body rested on the projecting end of the bone, causing great pain. It was alleged that the defendant was guilty of malpractice, in that he neglected to reset the bones within the first three weeks by manipulation, or in failing to perform an operation by cutting the foot open and pushing the dislocated wedge-shaped bone back into place. The jury returned a verdict for the plaintiff. The trial court entered judgment for the defendant notwithstanding the verdict.

On appeal it was held that, the facts being practically undisputed, the ultimate question was: Was it the duty of the defendant to attempt to set the dislocated bone by manipulation, or, the time passing when this might have been done, it being admitted that nature would grow new tissue as well as adapt the old tissue to the new situation, should the defendant have performed an operation? In some of its features the case seemed to the court to be one of first impression. So far as the main issue was concerned, it could make no more out of the record than that the defendant was charged with an error of judgment. The plaintiff put a medical witness on the stand who expressed the opinion that, if there was swelling and infection so as to prevent a resetting or an operation during the acute stage, an effort should have been thereafter made to restore the functions of the foot. The essence of his opinion was that the sooner the dislocation was reduced by one method or another the better. On the other hand, several medical men and surgeons of equal skill and judgment, so far as the record showed, were most positive in the opinion that the defendant was in no sense delinquent; that it would have been foolhardy, if not impossible, to reset the bone by any process until the wounds had healed completely and all danger of latent infection had passed; that the bruising or cutting of the new tissue necessarily incident to a resetting or an operation

would have been hazardous; that the bone would not have remained in place if set (not admitting that it could have been so set); that an operation might have made the infective germs, which may lie dormant after such an injury, active, resulting in the possible loss of the foot, or the life of the patient; that the duty of the surgeon under the conditions disclosed is first to look to the life of the patient. The treatment was described by one of the surgeons as a "monument of good surgery." The real question between the expert witnesses was when an operation might or should have been performed.

The Washington Supreme Court has uniformly held that where doctors of equal skill and learning, being in no way impeached or discredited, disagree on a given state of facts, the courts cannot hold a defendant in a malpractice case to the theory of one to the exclusion of the other. It is enough if the treatment employed has the approval of at least a respectable minority of the medical profession who recognized it as a proper method of treatment. The reason is obvious. A man who is called upon to exercise professional judgment is bound only to the exercise of reasonable skill, learning, and diligence. He is not liable for mistakes if he uses the method recognized and approved by those reasonably skilled in the profession. The court held that if men of skill and learning express contrary opinions upon admitted facts, although not preponderating the one way or the other (as they did in this case), the law would not impose a liability upon a professional man who acts within the reasonable limit of either opinion. Nor will a court hold a man guilty of malpractice when doctors disagree as to methods of treatment, although it be suggested that there is a more modern method to the exclusion of one therefore adopted as a standard. It therefore held that the defendant was not liable for malpractice up to the time when the plaintiff had left the hospital.

There was, however, another issue which the court did not decide without difficulty. It was within the bounds of all the opinion evidence that an operation at least to the extent of shaving or cutting off the end of the protruding bone would relieve the plaintiff of the pain incident to the present use of the member. It is the duty of a surgeon to do all that is reasonably necessary and reasonably within the limits of professional skill to relieve pain and suffering. Granting that the defendant had violated no duty up to the time the plaintiff left the hospital, it did not follow, under the testimony of his own witnesses, that he was released from his duty to operate at such time as the foot was in proper condition. He was under contract to treat the plaintiff. His duty was a continuing one, continuing to the limit of reasonable professional ability. It being reasonably clear that an operation was, at the time of the trial, necessary, and would probably relieve the physical suffering so far endured by the plaintiff—as to this there was no substantial difference of opinion—and the parties having offered evidence to show the reasonable cost of such operation, the court directed a judgment for the plaintiff of \$200.

The defendant was not held liable for the continued pain and suffering pending an operation. The reason was that he was not responsible for the original injury; he was answerable for proper care and treatment only. Under the plaintiff's own theory of the case that an operation should have been performed while he was still in the hospital, or within a reasonable time thereafter, he could not recover. At the time he consulted another surgeon, which was only a short time after he called on the defendant for the last time, he was advised that an operation would relieve him of his pain. He was under a legal duty to minimize his damages. It followed that he could not recover for the continued pain and suffering, or, to state the proposition in another way, it was the plaintiff's duty, if he conceived that he had been maltreated, to have an operation performed and bring suit for the reasonable cost thereof.—*Dahl v. Wagner*, Washington Supreme Court, 151 Pac. 1079.

Deceased Physician's Account Books in Evidence to Prove Litigant's Birth.—Under the "shop-book" rule an exception to the general rule against hearsay evidence, it is held that entries in the books of original account of a deceased physician, proved to be in his handwriting, tending to show the date of a litigant's birth, which was in issue, and as to which the physician, if living, would have been a compact witness, were admissible in evidence for that purpose.—*Sharp v. Blanton*, Alabama Supreme Court, 69, So. 889.

MEDICAL RECORD.

SARATOGA SPRINGS.

THE tenor of the remarks during the discussion on Saratoga Springs at the meeting of the Academy, reported in the present issue of the MEDICAL RECORD, would indicate that there is necessity for active participation on the part of every physician in the completion of the development of this Spa. The therapeutic value of carbonic acid waters has been too well established at Nauheim, Vichy, Marienbad, and other resorts to require further discussion. It remains now for American physicians to appreciate the fact that the carbonic acid waters of the Saratoga Springs are equal to those of any spa in Europe, and to strive as public-spirited citizens and physicians for the completion of the work of the Reservation Commission, which has skilfully wrested these valuable springs from the ruin threatened by those who were drawing out the carbonic acid gas and wasting the water for many years.

It appears from the historical résumé given by the former chairman of the commission, that the latter has wisely obtained the most expert advice and practical assistance for the restoration of the exploited springs. The results achieved testify to the judicious expenditure of the money appropriated by the Legislature from time to time, and warrant the urgent request by the Reservation Commission now being made for funds to complete the excellent original scheme for developing Saratoga into a health resort that will successfully rival any European one. It behooves the medical men of this State to address personal appeals to their representatives in the Legislature for support of the appropriation now before them. The Legislature has hitherto acted wisely in its caution with regard to the sums appropriated, following the general principle that commissions in charge of developments are naturally ambitious to excel, and regard all reductions of their estimates or budgets as niggardly. It would appear, however, that the present needs of the State reservation enterprise are not exaggerated. The future success of this Spa lies within our grasp, because the European war forces the seekers of health and recreation to resort to our own springs. If those who have hitherto visited the European resorts annually find these scientifically organized springs inadequate because of niggardly financial assistance by the State, failure must result that may handicap it for many years if not permanently, so that the large sums already

invested by the State will remain unproductive. If, on the contrary, the Legislature gives the necessary assistance without delay, for the time of preparation is all too short already, the satisfied visitors during the approaching summer will insure future prosperity and adequate return for the capital invested by the State. The Legislature should, however, act promptly in view of the brief period intervening between now and the opening of the season.

THE CONSUMPTION OF MEAT.

THE question of diet is beginning to receive that amount of consideration which its importance deserves, for in the prevention and treatment of disease it is now freely recognized that diet plays a large part. There are diseases which are caused directly by unsuitable foods and there are many diseases and conditions which may be prevented if due care is paid to the quantity and quality of the food ingested.

The undue consumption of meat has been regarded by many authorities as one of the main causes of digestive disturbances which may frequently lead to chronic constipation, intestinal stasis, and alimentary toxemia and which, according to Metchnikoff and Lane, bring about various diseases and affections of a more or less serious character. Especially has the contention been made that meat is the chief factor in the causation of arteriosclerosis, high blood pressure, and gout. Allbutt says that so far as the consumption of butcher's meat is concerned, one or two definite and separable crystalline products produced from proteins by bacteria, especially by a specific bacillus of the coli group, can affect the blood pressure.

Luff, in Sutherland's "System of Diet and Dietetics," ventures the opinion that the contention that a meat diet is poisonous to the human body on account of the uric acid it contains or produces is preposterous in view of the fact that many races have maintained robust health on such a diet, and that for centuries the beef-eating Britons have managed to spread and advance civilization, and to acquire territory in all parts of the world. It might also be mentioned that the Germans are large meat eaters and they seem to be fairly strenuous and active and exhibit no palpable signs of physical deterioration. Dr. Harry Campbell, in his series of articles on "The Evolution of Man's Diet," asserts, rather unconvincingly, that man has evolved from the ape on a highly animalized diet, and that it was on such a diet that the intellectual faculties and the power of language which distinguish him from the beast were developed.

The proteins of animal food are much more completely absorbed than those in vegetable foods. Meat is almost entirely consumed, about 97 per cent., and there is very little residue left in the bowel. This is, however, a manifest disadvantage. The percentage of residue in vegetable foods is very high. In potatoes 32 per cent. being left, while in carrots, beans, and lentils about 40 per cent. is left. The special value of proteins is that they are generally considered as the only true tissue builders and repairers. Muscle and

other tissues consist chiefly of proteins, and it is from the nitrogen containing proteins that they alone can be built. These, of course, can be obtained from vegetable foods as well as from those of animal origin. The ox, whose flesh is popularly regarded as the best "blood-forming" food, is typically a vegetarian.

With regard to the diet of an individual, and perhaps particularly with respect to the animal protein consumption, his age, his manner of life, and the climate must be taken into consideration. A man in the prime of life and vigor doing hard manual labor in the open air manifestly requires more food than the one who leads a sedentary life or is advanced in age. The vigorous hard worker can usually digest and assimilate large quantities of animal protein food. The man leading a sedentary life does not need so much food whether it be protein, carbohydrate, or fat, and whether it be animal or vegetable protein, and the man of advanced age whose powers are failing requires a food which places the least amount of strain upon the organs of digestion, assimilation, and excretion. It must be borne in mind, too, as Noël Paton says, that the availability of almost any article of food varies with the state of the teeth and the digestive organs of the individual, with the manner in which it is eaten, whether leisurely or too rapidly and without proper mastication.

While the pendulum of medical opinion seems to be swinging in the direction of a reduction in animal protein as an article of food for adults, it will not be wise to dogmatize too much as yet. There is little doubt that the habitual consumption of too little protein exposes the individual to a lowering of vitality, which expresses itself in a greater liability to suffer from infective disease. On the other hand, the consumption of too much protein unquestionably accelerates the progress of the degenerative diseases of heart, arteries, and kidneys.

DON'T BLAME THE CATGUT.

IN pursuance of the universal human tendency to seek for the causes of failure in our undertakings in the outside world rather than to conduct an introspective investigation, those surgeons who are indignant now and then at finding an infection following a "clean" operation are inclined to blame the suture material rather than to scrutinize closely every separate step of their technique. In most operating rooms a procedure has been outlined which is as the laws of the Medes and Persians and permits not of deviation. It is taken for granted that this technique is followed rigidly and surgeons and head nurses who remain in the operating room for years at a time are perhaps inclined to forget that assistants come and go. These subordinates, no matter how carefully they are instructed, may slur over some point as seeming of minor importance to them, and a chain is only as strong as its weakest link. Then, too, the sterilization of some part of the instruments, dressings, etc., is perhaps being done in a way that modern bacteriology has found to be inadequate, and yet this particular step in the process has never been re-

vised. Of course, these factors may be in existence for several months and the surgeon boast that he never has a stitch abscess, and then a strain of bacilli may find its way into the operating room and wounds become infected constantly, while the surgeon anathematizes everything and everybody, and finally lays the blame on the catgut, as it cannot defend itself and there is no one to defend it.

The real source of the trouble is more apt to be in the operating room technique somewhere, however. Writing in the *Modern Hospital* for December, a bacteriologist who signs himself merely "A Laboratory Technist" reports some of his investigations in operating rooms in an article which every surgeon should read. He visited by request first-class operating rooms throughout this country and Europe, and gave especial attention to those where apparently inexplicable infections had occurred. In each case he found one or more slips in the technique, and taking cultures at these points he usually found pathogenic organisms. In each case he used controls so that no suggestion of the non-sterility of his culture media is possible. In several cases he found a 5 per cent. carbolic solution used as the sole sterilizing agent of both basins and catgut containers; it is well known that this solution does not kill spores. In some cases he found only one wash basin or one soapy solution used by several persons or a soap container which it was necessary to tilt with the hand while using. Rubber gloves were "sterilized" by a single boiling in water, the fingers coming to the surface during this process, instead of weighting down the gloves and boiling them twice, reversed the second time. Catgut containers were found immersed in an aqueous bichloride solution, no other treatment being given them. In one case steam from the sterilizer collected on the ceiling of the room, condensed, and dropped into solutions and on instruments and dressings. One excellent surgeon observed scrupulous care about every detail of his technique, but still had infections. After minute observations the trouble was found to be this: The suture nurse, who had held retractors and assisted similarly in a "dirty" case, lifted up a corner of the sterile cloth covering the suture table, obtained the catgut for the infected case, and replaced the cover. The next case being a "clean" case, everyone changed gloves, fresh instruments were provided, but the suture table remained the same, being supposedly protected by the sterile cloth. In obtaining suture material for the clean case the nurse lifted up the same corner of the cloth, which had already been contaminated, fingered several tubes which she had touched during the previous operation, and selected a tube which she then broke and handled the inclosed material with gloved fingers which had become infected in the manner described.

It will be seen, therefore, that only a constant review of all the steps in an operation and a constant comparison of the methods used with recent bacteriological knowledge, as well as a testing of the technique at various points, can assure the surgeon that he is safe. At any rate, until one has satisfied himself that there is no fault to be found within his own doors, let him not blame the catgut.

SCARCITY OF MEDICAL MEN IN GREAT BRITAIN.

THERE is a dearth of doctors in Great Britain and when the exigencies of the situation are considered this is not to be wondered at. The British army at the commencement of the war was in the neighborhood of 350,000 men, and the Royal Army Medical Corps was barely sufficient for the needs of this number. Now that the army has expanded to perhaps 4,000,000 men, the strain on the resources of the country so far as the supply of medical men is concerned is necessarily extreme. Civil practice has become almost dislocated in consequence of the Government calling upon the young and able-bodied members of the medical profession to serve at the front in France and elsewhere and to attend to the wounded and sick in the hospitals in Great Britain, the elder men only being left for civil practice. Already the amount of work which has to be done by civil practitioners is almost beyond their strength, and continually more and more men are being demanded for the army. Moreover, it is certain that in the near future more severe fighting by the British will be waged than ever before and then the drain upon the civil practitioners will be intensified. In order better to cope with the state of affairs, a movement is now on foot to organize the civilian medical service, so that by promoting greater efficiency and better organization at home more medical men may be freed for the army.

The proposed scheme, it is said, is to divide the medical strength of the country into three groups according to age and physical fitness: (1) For service with the army and navy abroad; (2) For service with the army at home; (3) for civilian and public health and institution duties. It is proposed to place those under 35 years of age, who are physically fit for service, with the army in the field; in group 2, those over 35 years of age and under 50, and in group 3 the remainder of the medical profession. In Great Britain there are about 30,000 medical men registered. These have to serve an army amounting in round numbers to 4,000,000, a navy of 350,000, and a civilian population of about 40,000,000.

At the front the organization of the medical service is said to be very defective. There are many square pegs in round holes. Specialists are doing boys' work and young, unskilled men are performing grave operations. All this is to be changed and in future an expert will be set to do work requiring great skill and all medical men will be allotted work for which they are best fitted.

Persons are generally apt to regard the mote in their neighbor's eye and to neglect the beam in their own eye. The army medical service of the country is notoriously undermanned and as we may at any time have a war on our hands we would do well to see to it that the army medical service is reconstructed or rather remodeled on adequate lines. If a man is sufficiently patriotic to volunteer as a soldier, it is only right that his medical and surgical needs should be the object of scrupulous attention on the part of the Government. The serious dilemma in which Great Britain is placed by her scarcity of medical men and lack of organization should act as a warning to this country.

PENETRATING WOUNDS OF THE CHEST.

PENETRATING wounds of the chest have been of frequent occurrence in the present war, and the subject has been discussed at length in the medical journals of the various countries engaged. However, the matter is of sufficient importance to warrant reiteration, or, rather, it might be said that the views of different surgeons are valuable. Therefore a paper contributed by Dr. H. Perreau, surgeon to a French army ambulance, to the *Medical Press*, February 2, 1916, is in the fitness of things and should be instructive to surgeons everywhere. He first of all insists on immobilization of the patient, after a prompt diagnosis of a penetrating wound of the chest has been made, and further recommends that the immobilization should be sufficiently prolonged to obviate consecutive complications, or to mitigate their mischief when they do occur. Among these complications may be mentioned: (1) Embolism, which may be caused by any sudden movement, even after considerable time, and may prove rapidly fatal. (2) Pleural effusion, which is very common, serosanguinolent and hemorrhagic, soon becoming purulent. (3) Subcutaneous emphysema, either limited or more or less generalized. (4) Bronchopneumonia and hemorrhage from the lung are rarely met in ambulance hospitals because they are as a rule too rapidly fatal.

Perreau's conclusions are that in penetrating wounds of the chest the duty of the ambulance surgeons at the front is: (1) To make an early diagnosis, whenever possible by the aid of radio-scopic. (2) To secure immediate, absolute, and prolonged immobilization. (3) To keep the patients on water diet for the first two or three days, not allowing them to raise the head to drink. (4) Not to transfer such patients until after a fortnight's immobility. (5) To give during the first four or five days a daily dose of 10 c.c. of camphorated oil. (6) Except when conditions make it absolutely necessary, not to attempt the removal of the intrathoracic projectile. (7) To make promptly a wide opening to give issue to any purulent effusions.

WHOLE MILK FEEDING OF INFANTS.

THE methods of feeding infants, who for some reason, good or otherwise, are compelled to forego their natural means of nourishment and are condemned to artificial feeding, are many and various. There are physicians who pin their faith to one method and others who stoutly aver that another is the best. There is no agreement on any one form of artificial feeding. Eric Pritchard of London, England, who is one of the chief British authorities on the rearing of infants, has a paper in the January number of *American Medicine* criticizing the citrated whole-milk method of feeding. In the main he agrees that this gives good results, but he does not believe that it gives the best results. After many years of experimentation in his Infant Consultation at Marylebone, Pritchard has come to the conclusion that provided one is familiar with the principles of physiological feeding it makes very little difference what food one employs; whether, for instance, one uses dairy milk, so-called, dried milk, or condensed milk, provided certain essential conditions are complied with. These may

be stated as follows: (1) The necessary elements for growth, maintenance, heat production, energy production, and the elaboration of secretions must be supplied in the proportions and in the quantities required in each particular case. (2) These elements must be presented in a form capable of being digested and assimilated, and otherwise suited to the special physiological make-up of the infant to whom they are supplied. (3) The food must be of such a nature as to exercise and develop the latent digestive capacities preparatory to a more extensive dietary. After discussing favorably the dried milk method of feeding infants and emphasizing the point that there can be no such thing as a "best" food for infants, for the reason that the best food for each individual infant is that which is best adapted to its general physiological make up, and this will be different in each case—Pritchard concludes, with regard to the citrated whole milk method, that it is physiologically unsound, because it allows no latitude for adaptation to the digestive, assimilative, metabolic, and secretory activities of the individual baby and that its use implies obligatory modification on the part of the infant. If the principles of percentage feeding are understood, he says, synthetic foods can be prepared in a great variety of ways to satisfy the physiological requirements of particular babies.

SUCCESSFUL TRANSPLANTATION OF A TESTICLE.

CONSIDERABLE success in conserving the functions of the sexual organs under most unpromising circumstances has been reported in this country, notably by Lydston and Lespinasse, both of Chicago, but it is doubtful if any one has ever obtained a more clean-cut result than was claimed in a case recently reported by Lichtenstern before the K. K. Gesellschaft der Aerzte of Vienna (*Muenchener medizinische Wochenschrift*, December 21). A soldier had been badly wounded in the urethra and testicles, as a result of which he lost the power of erection and was without libido, while his general make-up began to approximate that of a castrate. There was in the same ward another soldier about to be operated on for inguinal testicle. When the latter was removed it was split in two and one-half was grafted into the musculature on either side of the middle line of the abdomen of the first patient. Within six days erections and libido returned and in the course of time the masculine habitus. The result in this case was remarkable, to say the least, and would seem to be attributable rather to a psychic action than to the establishment of an endocrinous functioning in so short a period. In discussion of the report, Tandler stated that the undescended testicle contains for the most part interstitial substance. He had often counseled this kind of implantation. Nevertheless the transplant would become absorbed in about two years, and the operation would have to be repeated.

TWO NEW JOURNALS.

WE have received the initial numbers of two new journals. *The Journal of Cancer Research* is edited by Richard Weil and the editorial committee of the American Association for Cancer Research. *The Journal of Immunology* is edited by Arthur F. Coca and has on its advisory and editorial boards practically all the leading immunologists of England and the United States. It is the official organ of

the Society for Serology and Hematology and the American Association of Immunologists. The appearance of these important members of the rapidly growing group of special journals in this country is, no doubt, due in part to the war which has closed the pages of so many foreign publications to American writers. Nevertheless, it is significant of the growing amount of productive research work which is being carried on here and will have a stimulating influence upon scientific circles. It is very gratifying that we are thus made independent of foreign periodicals, and there is no reason why these two publications should not become examples of the highest type of special journals. The contents of these two first numbers give high promise that such will in fact be the case.

News of the Week.

New York City Death Rate.—During the week ending March 18 the death rate in New York City was 14.39 per thousand of population, as compared with 16.63 for the corresponding week of last year, the total number of deaths being 1,541 and 1,743 respectively, an actual decrease of 202. Influenza, bronchitis, and Bright's disease were the only causes of death which showed an increased mortality; in all others a decrease was recorded. During the first twelve weeks of 1916 the death rate was 15.71, while for the corresponding period of 1915 it was 14.99, the higher rate being due to the epidemic of grip last January.

The Hay Bill Condemned.—At a meeting of the Medical Society of the County of New York on Monday of this week, the Hay military bill in Congress was strongly opposed on account of its provision for abolishing the Medical Reserve Corps in the Army, and a resolution was passed in favor of raising the strength of the Medical Corps of the Army so that there shall be, in time of peace, one surgeon to each 1,000 enlisted men.

Treatment for Rabies.—The Department of Health announces that on and after Monday, March 20, 1916, the Brooklyn Anti-Rabic Clinic at 29 Third Avenue will be open daily from 1 to 4 P. M. and on Saturdays from 1 to 3.30 P. M. On Sundays and holidays the hours will be from 10 A. M. to 12 noon, the anti-rabic service of the entire city being then cared for at the Brooklyn clinic.

Varicella and Whooping Cough.—Owing to the present low census of scarlet fever patients in the Willard Parker Hospital, New York, the Bureau of Hospitals is prepared to care for cases of whooping cough and varicella in the infectious stages of these diseases. Application for admission to the hospital should be made through the Bureau of Preventable Diseases, the procedure being the same as in cases of scarlet fever. Physicians in the Borough of Manhattan are invited to avail themselves of this opportunity for the care of those cases which are in need of hospital treatment.

Civil Service Examinations.—The United States Civil Service Commission announces an open competitive examination for men only for the position of assistant physicist, qualified in spectroscopy, there being a vacancy in the Bureau of Standards, Department of Commerce, Washington. The salary ranges from \$1,400 to \$1,800 per year, and the duties include the precise measurement of light waves and other spectroscopic research. The applicant must have received the degree of doctor of philosophy, or have had three years postgraduate

training in optics, including spectroscopy. The examination is open to all men meeting the requirements who are citizens of the United States and between the ages of 25 and 45. It will be held in various places in the United States on May 3, 1916. Applicants for the examination should apply at once to the Civil Service Commission, Washington.

On April 25, 1916, the commission will hold an examination for the purpose of filling a vacancy in the position of chief statistician for vital statistics (male) in the Bureau of the Census, Department of Commerce, Washington, at a salary of \$3,000 a year. The chief statistician is the administrative and statistical head of the Division of Vital Statistics and has full charge of the work therein. Graduation from a recognized medical school and at least four years' experience in charge of the vital statistics of a city or State, or in a position of similar importance requiring expert knowledge of vital statistics are prerequisites for this position. Special credit will be given for experience in the practice of medicine and in positions of an executive character. Applicants must be between the ages of 30 and 50, and must have been actually domiciled in the State or territory in which they reside for at least one year previous to the date of the examination. Application blanks may be obtained from the office of the United States Civil Service Commission, Washington, D. C.

Hospital Ship Reported Torpedoed.—Reports from Berlin state that the hospital ship *Elektra*, in the Austro-Hungarian Red Cross service, was torpedoed on March 18, while bound from the North Adriatic to South Dalmatia.

Isaac L. Rice Memorial Hospital.—The incorporation of the Isaac L. Rice Memorial Hospital for convalescents, which, as announced last week, is to be built at Irvington, N. Y., is provided for in a bill introduced in the New York State Legislature on March 21. The object of the incorporation is stated to be the establishment of a non-sectarian hospital for the gratuitous care of patients recovering from illness.

Opposition to the Mount Sinai Pay Clinics.—The following resolution was unanimously adopted at a meeting of the Medical Society of the County of New York, held on Monday evening of this week:

"It is proposed by a large hospital in this city to establish a night clinic for the medical and surgical treatment of persons on the general basis of \$1 a visit. A provision is also made that the institution will endeavor to confine its aid to persons having incomes of \$1,200 a year or less. It is evident that this method could be ultimately extended to every hospital in the city and take a large section of the general and special practice from the profession and place it in the hands of medical institutions.

"Whereas, Past experience has shown the impossibility of limiting the benefits of medical charity to those entitled to it by an arbitrary income rating;

"Whereas, Employed persons earning \$1,200 a year are by no means objects of medical charity;

"Whereas, Employed persons earning the above income are a very large part of the clientele of the general practitioner and specialist;

"Whereas, Hospital dispensaries have been established to care for the sick poor only;

"Resolved, That the Medical Society of the County of New York condemns and opposes the scheme

of pay night clinics in medical institutions as an unnecessary pauperization of individuals and as an injury to the medical profession."

Mind Test for City Lodgers.—Commissioner of Charities Kingsbury of New York City has recently appointed a committee to formulate a plan for examining the mental condition of applicants at the Municipal Lodging House. The examinations will be carried out for the purpose of determining what work the men are capable of doing. The committee consists of Dr. Menas G. Gregory of Bellevue Hospital, Dr. August Hoch, director of the Psychiatric Institute of the New York State Hospital, and Dr. Thomas W. Salmon, medical director of the National Committee for Mental Hygiene.

Medical Society Election.—At a meeting of the Homeopathic Medical Society of Western Massachusetts in Springfield, Mass., on March 15, the following officers were elected: *President*, Dr. E. W. Capen, Monson; *vice-presidents*, Dr. J. W. Crawford, North Adams, and Dr. Bina Seymour, Springfield; *secretary-treasurer*, Dr. M. W. Conrow, Springfield.

The Influence of the Medical Profession in World Reconstruction is the title of a lecture to be delivered by Dr. F. E. Sondern, president of the Medical Society of the County of New York, on Sunday, April 2, at 10 A. M. in Mt. Morris Baptist Church, Fifth Avenue, between 126th and 127th Streets. The lecture is open to all, but members of the medical profession are especially invited. Dr. A. Jacobi will introduce the speaker. At 9.30 A. M. there will be an informal reception to Dr. Sondern in the church parlors.

Personals.—Miss MARY KATHERINE WOLFE of New York, a volunteer nurse who has been connected with the American Ambulance in Paris since the institution was opened, has received from the French Government the silver medal as an acknowledgment of her self-sacrifice and devotion.

Dr. JOHN G. STANTON of New London, Conn., has been appointed a member of the Connecticut State Board of Education.

Dr. EVA HARDING of Topeka, Kan., has announced that she is a candidate for the Democratic nomination for congressman, on a platform opposing militarism, and favoring national prohibition, woman suffrage, and mothers' and old age pensions.

Obituary Notes.—Dr. CHARLES MARTIN CAMPBELL of Paterson, N. J., a graduate of the Bellevue Hospital Medical College, New York, in 1894, a member of the American Medical Association, the Medical Society of New Jersey, and the Passaic County Medical Society, and physician to St. Joseph's Hospital, died at his home, March 20, aged 59 years.

Dr. CARLOS E. HUSK whose death at Laredo, Tex., was reported last week was a graduate of the University of Illinois, college of medicine, in 1898, and was 43 years of age. Dr. Husk was chief surgeon of the American Smelting and Refining Company. He had joined the Mount Sinai Hospital doctors who were studying typhus in Mexico, and contracted the disease in the course of his investigations.

Dr. WILLIAM S. S. GAY of Cleveland, Ohio, a graduate of the Jefferson Medical College, Philadelphia, in 1869, died at his home on February 26, aged 70 years.

Dr. GASPARD UPTON PELTIER of Cohoes, N. Y., a graduate of the University of Bishop College, Faculty of Medicine, Montreal, in 1873, died at his home

on March 2, aged 67 years. Dr. Peltier was, until recently, city physician of Cohoes.

Dr. SAMUEL H. LINN of Rochester, N. Y., a graduate of the Medical Department of the University of Pennsylvania, Philadelphia, in 1877, died at his home on February 28, aged 72 years.

Dr. EDWARD J. CUNNINGHAM of Philadelphia, a graduate of the Medical Department of the University of Pennsylvania in 1900, died at his home on March 2, aged 38 years.

Dr. JOHN JACOB DETWILER of Easton, Penn., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1854, and a life member of the American Homeopathic Society, died at his home on February 28, aged 82 years.

Dr. CHARLES HAROLD GOLDSMITH of New York, a graduate of the Eclectic Medical College of the City of New York in 1906, and of the Long Island College Hospital, Brooklyn, in 1910, died at his home on February 29, aged 43 years.

Dr. GEORGE LANE TANNEYHILL of Baltimore, Md., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1865, died at his home on March 2, of heart disease, aged 76 years. Dr. Tanneyhill was a member of the American Medical Association, the Medical and Chirurgical Faculty of Maryland, the Baltimore City Medical Society, and the Association of United States Military Surgeons.

Dr. OSCAR HOWARD MORRIS of Rockmart, Ga., a graduate of the Southern Medical College, Atlanta, in 1898, died at his home on February 20, aged 41 years.

Dr. LOOMIS C. BLANTON of Blanton Station, Ky., a graduate of the Hospital College of Medicine, Louisville, in 1906, died at his home on February 21, after an illness of six months, aged 33 years.

Dr. WILLIAM LEET KREIDER of Prairie City, Ill., a graduate of the Rush Medical College, Chicago, in 1859, died at his home on February 19, from a paralytic stroke, aged 84 years.

Dr. CLARENCE F. COCHRAN of Griffith Station, Arvado, Col., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1873, died at his home on February 18, aged 66 years.

Dr. ALICE AMELIA GOODRICH of Des Moines, Iowa, a graduate of the State University of Iowa, College of Homeopathic Medicine, Iowa City, in 1889, died at her home on February 20, aged 64 years.

Dr. THOMAS BOYD MORRIS of Atlantic, Iowa, a graduate of the Rush Medical College, Chicago, in 1900, died in the Atlantic Hospital on February 19, from injuries received in an automobile accident, aged 50 years. Dr. Morris was a member of the American Medical Association, the Iowa State Medical Society, the Cass County Medical Society, and the Botna Valley Medical Society.

Dr. DAVID P. MILLER of Huntingdon, Pa., a graduate of the Jefferson Medical College, Philadelphia, in the class of 1884, died of uremia, at his home on February 16, aged 80 years.

Dr. BUCKNER FAIRFAX SCOTT of Terra Alta, West Va., a graduate of the Jefferson Medical College, Philadelphia, in 1906, and a member of the West Virginia State Medical Association and the Preston County Medical Society, died suddenly at his home on February 21, aged 37 years.

Dr. JOHN A. DOWELL of Albany, Ind., a graduate of the Eclectic Medical College, Cincinnati, in 1881, was killed by a train February 19, while on his way to visit a patient. Dr. Dowell was 58 years old.

Dr. ALLEN WALKER of Washington, D. C., a grad-

uate of the University of Maryland School of Medicine, Baltimore, in 1886, and a member of the Medical Society of the District of Columbia, died at his home on February 21, after an illness of six months, aged 64 years.

Dr. CHARLES TEBBS PEPPER of Los Angeles, Cal., a graduate of the Jefferson Medical College, Philadelphia, in 1869, died at his home on February 19, after a long illness, aged 69 years.

Dr. LUTHER ORIN MARTIN of Springfield, Mass., a graduate of Columbia University, College of Physicians and Surgeons, New York, in 1875, died suddenly at his home on February 26, aged 64 years.

Dr. JULIUS HENRY MOORE of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1874, died at his home, on March 11, aged 79 years.

Dr. HENRY BETZ of Brooklyn, N. Y., a graduate of the New York University Medical College in 1886, died at his home from pneumonia, on March 12, aged 58 years.

Dr. CHARLES O. MAINE of Stonington, Conn., a graduate of the Dartmouth Medical School, Hanover, in 1871, died at his home after a lingering illness, on March 12, aged 73 years.

Dr. WILLIS A. MERICK of Monticello, Ia., a graduate of the Hahnemann Medical College and Hospital, Chicago, in 1878, and a member of the Iowa State Medical Society and the Jones County Medical Society, died suddenly from heart disease at his home, March 1, aged 62 years.

Dr. BENJAMIN FRANKLIN CAMPBELL of Brookline, Mass., a graduate of the Harvard University Medical School in 1857, died at his home, March 9, aged 82 years. During the Civil War Dr. Campbell was acting assistant surgeon in the army of the Potomac.

Dr. JAMES C. BLICKENSDECKER of Denver, Col., a graduate of the Washington University Medical School, St. Louis, in 1877, and a member of the Colorado State Medical Society and the Denver City and County Medical Society, died suddenly from heart disease at his home, March 3, aged 69 years.

Dr. JAMES LANIER DARWIN of Huntsville, Ala., a graduate of the Bellevue Hospital Medical College, New York, in 1888, and a member of the Medical Association of the State of Alabama and the Madison County Medical Society, died from heart disease in Memphis, March 3, aged 57 years.

Dr. M. F. SCRUGGS, a graduate of the University of Louisville, Medical Department, in 1882, and a member of the Mississippi State Medical Association, and the Marshall County Medical Society, died suddenly at his home near Holly Springs, Miss., March 2.

Dr. GUSTAVE ADOLPH KRAUSS, formerly of Jersey City, N. J., a graduate of the New York University Medical College in 1898, died in the Trenton State Insane Asylum, March 16.

Dr. JOSEPH A. TREMBLAY of Butte, Mont., a graduate of the Victoria University, Medical Department, Toronto, in 1869, died from heart disease at his home March 6, aged 70 years.

Dr. PATRICK JOSEPH BARRY of Carroll, Ia., a graduate of the State University of Iowa, College of Medicine, Iowa City, in 1891, died at his home recently, aged 49 years.

Dr. ASA STEWART IGLEHART, formerly of New York, a graduate of the New York University Medical College in 1897, and a member of the Alumnae of St. Luke's Hospital, died at his home in Iquique, Chile, on March 18, aged 46 years.

Dr. EMLEN PHYSICK of Cape May, N. J., a graduate of the University of Pennsylvania, department of medicine, Philadelphia, in 1897, and a member of the Medical Society of New Jersey and the Cape May County Medical Society, died suddenly, from apoplexy, at his home, March 21, aged 58 years.

Dr. CHAUNCEY S. LAMB of New Haven, Conn., a graduate of the University of Buffalo, medical department, in 1893, and a member of the Connecticut State Medical Society and the New Haven County Medical Society, died at his home, March 23, aged 44 years.

Dr. BERNARD WOLFF of Atlanta, Ga., a graduate of the University of Virginia, department of medicine, Charlottesville, in 1888, died at St. Joseph's Infirmary, March 22, following an operation, aged 49 years. Dr. Wolff was clinical professor of diseases of the skin in the Atlanta College of Physicians and Surgeons, and was a member of the American Medical Association, the Medical Association of Georgia, and the Fulton County Medical Society.

Dr. WILLIAM H. CAMPBELL of Cincinnati, Ohio, a graduate of the Miami Medical College, Cincinnati, in 1891, died suddenly in Los Angeles, Cal., aged 54 years. Dr. Campbell was a member of the American Medical Association, the Ohio State Medical Association, the Cincinnati Academy of Medicine, and the American Academy of Ophthalmology and Otolaryngology.

Dr. J. E. BROWN of McGregor, Tex., a graduate of the medical department of the Tulane University of Louisiana, New Orleans, in 1888, died from Bright's disease, at his home, March 13, aged 51 years.

Dr. THEO. MCL. NORTHRUP of St. Paul, N. C., a graduate of the University of Maryland, school of medicine, Baltimore, in 1897, and a member of the American Medical Association, the Medical Society of the State of North Carolina, and the Robeson County Medical Society, died from Bright's disease at the Charlotte Sanatorium, March 13, aged 46 years.

Dr. EDMUND R. P. FORTIN of Waltham, Mass., a graduate of the Harvard University, medical school, in 1890, and a member of the Massachusetts Medical Society, and the Middlesex District Medical Society, died suddenly, March 15, aged 50 years.

Dr. FRANK J. LUTZ of St. Louis, Mo., a graduate of the Washington University Medical School, St. Louis, in 1876, died from heart disease at his home, March 24, aged 61 years. Dr. Lutz was chief surgeon of Josephine Hospital, attending surgeon of the Barnard Free Skin and Cancer Hospital, and professor of surgery in Washington University, St. Louis. He was a Fellow of the American College of Surgeons, and a member of the International Surgical Association, the American Surgical Association, the St. Louis Surgical Society, the American Medical Association, the Missouri State Medical Association, and the St. Louis County Medical Society.

Dr. WILLIAM GEORGE SIEGEL of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1910, and assistant surgeon on the staff of Trinity Hospital, Brooklyn, died at his home, of pneumonia, after a brief illness, on March 25, aged 28 years.

Dr. GRANVILLE PRIEST CONN of Concord, N. H., a graduate of the Dartmouth Medical School, Hanover, in 1856, died, March 24, at Wayne, Pa., aged 84 years. Dr. Conn was emeritus professor of hygiene in the Dartmouth Medical School, and

was president of the State Board of Health. He was a member of the American Medical Association, the New Hampshire Medical Society, acting at different times as secretary, vice-president, and president, the District Medical Society, the International Association of Railway Surgeons, and the Medicolegal Society of New York.

Dr. EDWARD D. PAYNE of Towanda, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1857, by act of Congress, medical director in the United States Army, having entered the service in 1861 and served until 1876, and a member of the Medical Society of the State of Pennsylvania and the Bradford County Medical Society, died at his home, on March 24, aged 81 years.

Dr. THOMAS B. EARLEY died of bronchopneumonia at Philadelphia, March 21, at the age of 49 years. He was graduated from the Medico-Chirurgical College of Philadelphia in the class of 1890. He was a member of the Philadelphia County Medical Society, and of the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Obituary.

GUSTAV ADOLF LANGMANN, M.D.

NEW YORK.

DR. GUSTAV A. LANGMANN died at his home in this city on Monday of this week of cardiac disease. He was born in Mecklenburg in 1842 and was graduated from the University of Greifswald in 1866. Three years later he came to New York and had practised here since that time. He was a member of the New York State and County Medical Societies, of the American Medical Association, the New York Academy of Medicine, the German Medical Society, the New York Pathological Society, and the American Association of Pathologists and Bacteriologists, and was attending physician to the German and Mt. Sinai Hospitals. Dr. Langmann was an authority on poisonous snakes and snake venom, and was the author of the article on "Poisonous Reptiles" in the Reference Handbook of the Medical Sciences, and of other articles on this subject in various scientific publications.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TRENCH NEPHRITIS—CEREBROSPINAL FEVER—
OBITUARY.

LONDON, March 4, 1916.

THE Royal Society of Medicine has held a combined meeting of its sections on Medicine and of Pharmacology and Therapeutics for a discussion on trench nephritis. It was opened by Sir William Osler, who had not found previous accounts of the disease, except some cases reported as occurring during the American Civil War. Its clinical characters are those of ordinary acute nephritis, coming on usually without previous disorder, but with slight differences; thus the edema is transient and generally local, while anasarca is rare. Dyspnea is prominent and slight fever has been noted in a few of the cases which have returned to England. Probably this is more frequent in the earlier stages. The dropsy disappears rapidly when improvement

sets in, and restoration to seemingly good health may often be observed while the urinary symptoms and high blood pressure continue. Cases had been admitted to St. Bartholomew's Hospital having albumin with casts and blood in the urine but without history of dropsy. Recovery was the rule, but some cases had been fatal. Three post mortems had been made: in one a typical large milky-white kidney was found identical with Bright's description except for the absence of infected stellate veins. There was no sign of fatty degeneration. In Case 2 acute nephritis seemed planted on an old nephritis. In Case 3 death occurred from intercurrent pleuropneumonia; but the kidneys were sclerotic with marked recent tubular and glomerular nephritis. In two other fatal cases no necropsy was made; they had died from rapid uremia. Sir William feared many of these cases would become chronic and considered it highly probable they would do so if the albumin continued in the twelfth week.

Professor Andrews had examined specimens from six cases and exhibited the sections. Only one was at an early stage; in that sudden death followed cerebral hemorrhage. The others were typical examples of severe trench nephritis and showed changes in the glomeruli, tubules, and interstitial tissue; in the glomeruli the usual proliferation of the epithelium of the capsule; in the tubules degeneration and desquamation of the epithelium. Few fatty changes, or none; some cellular infiltration in the interstitial tissue, the infiltrating cells being chiefly leucocytes, while plasma cells were absent. This corresponded with the condition of the urine, from which a deposit of leucocytes was noticeable. So many polymorphonuclear cells appeared in one case that pyelitis was suspected. An example of old-standing nephritis had superimposed on it the trench nephritis. There was nothing to distinguish it from other varieties of nephritis; the acute glomerular form of scarlatina was comparable with it in all respects.

Dr. Mackenzie Wallis spoke of the value of estimating the diastatic output as an index to the efficiency of the renal tubules; in no other disease was this so low. As the ferment is secreted by these tubules, its diminution indicates the amount of damage. The test is further of use in prognosis; diastase may diminish after albumin has disappeared. Casts, mostly hyaline, were always present, as was a relative excess of white corpuscles as in the scarlatinal form. In some cases retention of nitrogen even after the diastase excretion has become normal, a point to consider respecting the ability of the patient to resume employment. The urine is remarkably toxic, but the chemical characters of the toxin have not been determined. Two animals infected died in six days of albuminuria, but in post mortem no evidence of nephritis was found. Urine produced no symptoms if it were previously heated to 55° C., but an unheated filtrate did.

Capt. R. G. Abercrombie had worked in France and spoke of having seen about 500 cases in the acute stage. They presented the characteristics of acute nephritis of medium severity. Headache and dyspnea were constant, blood pressure varied from 30 to 60 mm. of Hg, the morning reading low, the evening high. On first fever, the temperature about 101° Fahr. In about half the cases premonitory symptoms were bronchitis, pains in back, limbs, and abdomen, and vomiting. In

one group there were symptoms suggestive of pyelitis, cystitis, or prostaticitis, but no fever, edema, or blood pressure, though casts might occur in the urine. Of about 500 cases, four were fatal—one in the first week. In this there were but slight ordinary changes in the kidneys, but the microscope revealed the tubules with some interstitial change; spleen was large; tracheal mucous membrane granular. The cases were scattered, but chiefly in small definite epidemics at the front and in certain areas. His impression was that the disease is infective.

The report of the special advisory committee appointed by the Medical Research Committee (National Health Insurance) on bacteriological studies of cerebrospinal fever during the epidemic of the first eight months of 1915 has been published. The members of this committee were Profs. F. W. Andrewes, W. Bulloch, and R. T. Hewlett, and their report is based on the results of experience in different laboratories throughout the country, and also on reports transmitted to the committee by workers engaged in the study and control of the disease among the military forces.

Surgeon-General Ch. Edwin McVittie, late of the I. M. S., Hon. Physician to the King, has died at Exmouth. He had been Hon. Physician to Queen Victoria from 1898 to 1901, to King Edward during his reign. He received a distinguished service reward in 1894 and retired in 1900. He was a Fellow of the Edinburgh College of Physicians and of the Irish College of Surgeons. He served in the Afghan War in 1880, for which he had the medal, and with the Burmese Expedition in 1886-7, when he was mentioned in dispatches and received the medal with two clasps.

Deputy Surgeon-General Eugene Francis O'Leary has died at Sidmouth in his eighty-first year. He entered the army in February, 1856, and was placed on the retired list in December, 1883. He served many years in India and China and was in the Egyptian campaign in 1882, for which he received the medal and the Khedive's star.

3. How can We Detect Slight Enlargements of the Heart? George Cheever Shattuck.
4. Recent Progress in Psychiatry. Henry R. Stedman.

3. How Can We Detect Slight Enlargements of the Heart?—George Cheever Shattuck states that if slight cardiac enlargement is to be detected, that is, an increase of two or three centimeters in the transverse diameter of the heart, the first essential is an adequate standard of the normal. He reviews the work done in this direction by Veith, Groedel, Dietlin, and Clayton and Merrill. He states that the tables of Groedel are valuable for providing maximal, minimal, and average figures of normal heart size, but that the relation of the figures to stature is not clearly apparent. Dietlin founded his figures on the relation of the heart size to body weight, which method Shattuck considers the correct one. He summarizes as follows: that heart size is dependent first on body weight, and second, apparently on age, and that stature *per se* is not important; that tables of heart size based on stature are not satisfactory. The tables of Clayton and Merrill are based

on weights, and their table for men is divided into six groups. The first four groups ascend by ten pounds and the last two by twenty pounds. That for women ascends by ten pounds in six groups, and in the seventh by fifteen pounds. The maximum weight for women is one hundred seventy-five, and for men two hundred pounds. The authors point out that there is a rapid increase of heart size in men up to one hundred twenty-eight pounds of body weight, and after that the increase is more gradual. In the higher weights, the increase is very slight. The increase in women was found to be less marked. Other factors influencing heart size or heart measurements are occupation, posture, size and depth of the chest, change of position due to breathing, the effect of corset pressure in women, and the position of the diaphragm, which Shattuck says seems to be the most important of all factors. The normal heart varies in shape and position. Clayton and Merrill's figures for men show variations of 4.0 centimeters within the normal for the greatest distance from the median line to the left horizontally, designated as "ML"; Groedel found differences of 3.0 centimeters and Dietlin of 3.6 centimeters. A heart originally small might become pathologically enlarged by three centimeters, or even more, before this could be detected by measurements alone; but, in such a case, if nutrition, position of diaphragm, and age, when necessary, were considered, it might be possible to discover enlargements of not more than two centimeters. Shattuck quotes Groedel's four measurements for heart size, namely, the greatest distance from the median line to the right horizontally designated as "ML," a similar measurement to the left, "MR," the sum of these two, the transverse diameter, "T," and the length, measured from the apex to the angle formed by the junction of the curve of the great vessels with that of the right border, known as "L." Shattuck calls attention to the importance of skillful physical examination and careful history as means of discovering abnormality in the circulatory system and slight signs of enlargement of the heart; when these are inconclusive the x-ray, fluoroscope, or orthodiagram, or a teleoroentgenogram may clear up the outline or measurements of the heart.

mastoid process. If the mastoid infection occurs in the immediate proximity of the middle ear, it is more than probable that free drainage of the tympanum will relieve the mastoid infection. How can we tell in a given case of acute aural suppuration that there will be probably serious mastoid involvement, or how can we tell that any involvement has disappeared, when the middle ear condition has completely recovered? The site of the inflammatory process is important. Inflammations confined to the lower part of the tympanic cavity are less liable to be followed by serious mastoid infection, than when the upper part of the cavity is involved. Middle ear involvement which does not resolve very definitely at the end of two weeks is one of mastoid involvement sufficiently extensive to demand at least exploratory operation. Local tenderness is a very valuable sign and appears in a large proportion of cases, but its presence is not always indicative of mastoid involvement. Tenderness at the beginning of an attack of acute otitis is of comparative insignificance; tenderness which appears after the fourth or fifth day of the attack is of great significance. Tenderness over the mastoid antrum is of more value as a diagnostic sign than tenderness over the tip. The nature of the infection is another diagnostic aid. A staphylococcus infection does not usually involve the mastoid; but a streptococcus demands careful watching, and the mastoid process should be opened up earlier than would be the case with a milder infection. Dench places his dependence on the state of the external auditory canal. In the majority of his cases of difficult diagnosis of mastoid condition, the external auditory canal showed decided narrowing near the drum membrane. Not the bulging of the drum membrane, but the actual shortening of the external meatus occurs, in many of these cases. Ordinarily there is symmetry of the external auditory canals. A symmetry between the two is to be regarded with suspicion, and with the history of acute otitis a narrowing of the deeper portion of the canal is almost pathognomonic of mastoid involvement. At the present time his operative findings always agree perfectly with the radiographic pictures, but it needs study, both before and after operation, of the plates in order that the full value of this method of diagnosis may be obtained.

1. Obscure Cases of Mastoid Involvement.—Edward B. Dench states that there are a large number of cases of mastoid involvement in which the development of the inflammatory process is so insidious, and the symptoms are so slight, that a diagnosis is made with the greatest difficulty, even by those who have seen a large number of cases. He cites several cases of his own, in which there had been middle ear involvement to a slight extent, but which had cleared up apparently, until, as in one case, a persistent headache, and in another case, a narrowing of the external auditory canal and lack of drum membrane lustre, caused him to search for the cause, to find it in each case in a mastoid involvement. Operation cleared up the condition. He says that the actual cessation of discharge in middle ear condition is no absolute indication that the mastoid is healthy. Infection of the middle ear always means infection of the

3. History of Intravenous and Subcutaneous Administration of Drugs.—David I. Macht considers it to be our duty to ascertain as far as possible and to commemorate the names of those who discovered or invented the above-named procedures and remedies. Transfusion of blood is said to have been practised among the Egyptians. The earliest explicit record of it was in 1492, when it was recommended for the treatment of Pope Innocent VIII. It was Sir Christopher Wren, professor of astronomy at Oxford, who first tried the experiment of injecting drugs into the veins of animals in 1656, and in 1657 repeated the experiment on man. Opium was one of the first drugs injected, and syphilis was one of the first diseases treated by intravenous injection. The second period in the history of this work began about the end of the eighteenth century and extended to the middle of the nineteenth century, while the third period extended from then to the present time. The second period covered experimental work along toxicological and pathological lines, and in this connection are noted the names of Fontana, Magendie, Bichat, Nysten, and others. Baron Magendie and Percy attempted to cure tetanus and hydrophobia by intravenous injections, publishing reports in 1814 and 1823. Halford, in 1869, reported results of his experiments on the injection of ammonia in cases of snake bite. The third period is distinguished by the development of bacteriological knowledge, and injections were made either to increase the patient's resistance to infection or for the destruction of the agents of infection. Under the first comes the injections of balsam of Peru and later of sodium cinna-mate in tuberculosis by Landerer in 1892, and the injections of sodium cacodylate for pernicious anemia and other conditions by Gautier about 1897. Under the second heading comes the work of Baccelli in 1890 on intravenous injections of quinine in malaria, and the work of Credé in 1901 on the injection of silver salts in all kinds of infections. The discovery of hypodermic injections was a great intellectual achievement. The epidermatic method, also the endermic method, was first used. These were followed by the inoculation method used extensively when LaFarge, in 1836, proposed its use for other remedies than cowpox virus. The invention of hypodermic injections in therapeutics was first made by an Irish surgeon, F. Rynd, in 1844, or about ten years earlier. Macht credits Pfender of Washington, D. C., with this valuable information, for Alexander Wood of Edinburgh has been given the credit of this discovery in 1853. Wood, however, applied this method of drug administration to a large number of cases, wrote up his work, and considered that the maximum effect from the hypodermic was exerted at the place of injection. Charles Hunter in 1859 demonstrated that it is unnecessary to make the injection at the seat of pain. Ruppaner of Boston introduced the hypodermic method of medication into the United States, and John S. Billings tells of its use in the Civil War. Rynd used a syringe devised by himself; Wood first used one made by Ferguson, while the hypodermic syringe of Charles Pravaz of Lyons is the prototype of the hypodermic syringe of today.

4. A Rational Treatment of the Morphine Habit.—Charles E. Sceleth outlines the method of treatment he has employed for the cure of the morphine habit. There are many angles to the plan; its essence rests in the formula: scopolamine hydrobromide, gr. 1/100; pilocarpine hydrobromide, gr. 1/12; ethylmorphine hydrochloride, gr. ½; fluidextract cascara sagrada, m. 15; alcohol, m 35; water, qs. ad 5 1. The amount prescribed and the indications for its continuance or modification vary with the case. Patients who are addicted

to the use of more than 10 grains of morphine a day are given 60 minims of the mixture every three hours, day and night, for six days. This is reduced to 30 minims on the seventh day, to 15 minims on the eighth day, and on the ninth day to 15 minims three times during the day only. On the tenth day the mixture is discontinued altogether and tonic treatment begun. Addicts accustomed to the use of less than 10 grains of morphine a day and more than five are started with a dose of 45 minims, which is reduced on the seventh day in a manner analogous to that just detailed; to those who have been taking less than 5 grains, only 30 minims are given as an initial dose. If on the third or fourth day of treatment the pupils are dilated and react to light and accommodation, the patient is reacting properly and the outlook is good. The patient on admission is put to bed, given three compound cathartic pills, followed by a saline cathartic (Epsom salt), and at once started on the scopolamine mixture. During the first few days the diet should be light and liquids should be pushed, the patient drinking 3 pints or more of water a day. On the tenth day strychnine nitrate, gr. 1/30, is given for three doses; the following day the amount of strychnine is reduced to gr. 1/60, which is continued three times a day for a week. By the fifth day the patient's desire for morphine is gone. A substantial diet is requested and he begins to put on weight rapidly. Graded exercises are begun, if possible, in order to promote strength and induce bodily fatigue, which combats the insomnia. A warm bath and carbonated waters aid in this effort. Sceleth says that there is no specific treatment for the morphine habit, but the above-outlined plan seem to meet most accurately the specific indications from the pharmacological point of view. Other advantages of this regimen are its simplicity, because it can be carried out in a private hospital or home and by the non-specialist, and its freedom from abstinence symptoms, especially the more dangerous ones. No plan of therapy, however logical or successful, can assure freedom from recurrence. This is entirely a matter of the individual. One with no natural force of character, or one who returns to a former vicious environment, is likely to relapse; while the man of higher type who is anxious to reform is capable of doing serious work and, if given the opportunity, has an excellent chance of permanently remaining cured.

5. Treatment of Cases of Epidemic Meningitis.—Josephine B. Neal states that the most common two mistakes in serum treatment of epidemic cerebrospinal meningitis seem to be giving too few doses of serum, if the patient improves considerably after the first one or two injections, and failing to persist with the serum if the improvement is very slow. It has been the experience of the meningitis department of the Bureau of Laboratories, Department of Health, New York City, during the past five years that it is rarely safe to give less than four doses of serum on consecutive days, even if the improvement clinically is very rapid and the organisms disappear from the fluid after one or two injections. In cases which have been running on for some time and in which the patients are evidently improving when first seen, one or two injections of serum are sometimes sufficient. A case of average severity usually requires from four to seven injections. It is safer to give the injections on consecutive days until it seems evident that the patient is out of danger than to skip a day or two when a slight improvement occurs, thereby giving the organism a chance to increase. Puncture for the relief of pressure may have to be done several times during convalescence, and at such punctures a little serum may be injected, especially if a large amount of fluid be withdrawn. In a small per-

centage of cases—from 5 to 10 per cent.—a large number of injections may be necessary before the termination of the case, and a certain number of such cases terminate fatally. Autogenous vaccines have not been used in a sufficient number of cases to show their value definitely, but Neal says that it is the custom of the department to use them in cases that tend to become chronic and in a number of cases they seem to have been beneficial. It has been the experience of the department that doses of serum larger than 20 c.c. need to be given with extreme caution, even though very large amounts of fluid are withdrawn. Untoward effects from the withdrawal of large quantities of fluid have never been observed. The punctures are always made with the patient lying down. The serum treatment should be continued until the fluid has been sterile for two or three days and until the patient clinically is much improved. Hexamethylenamin is given as a routine. It certainly tends to prevent cystitis if retention develops, as it often does. Sedatives must be used if the patient be delirious or restless, preferably some preparation of opium, as it has a less depressing effect on the heart. The eyes, mouth, skin, and bladder, and bowels all must receive careful attention. Most important of all is the feeding, for in many instances swallowing is very difficult on account of the retraction of the head, and the greatest patience must be exercised to induce the patient to take even a little nourishment.

14. Variations in the Strength of Positive Wassermann Reactions in Cases of Untreated Syphilis.—David A. Haller states that the explanation sometimes offered for the difference in the results of the Wassermann reaction on the same individual done at different laboratories is that antigens have been used which vary in strength. He reports that in a recently completed series of more than 6,000 Wassermann reactions done on the serum from 5,000 individuals at the medical clinic of the Peter Bent Brigham Hospital, Boston, only one antigen has been made use of, so that any variation reported here cannot be attributed to this factor, as this antigen for all practical purposes is constant. A group of twenty cases of untreated syphilis including all stages of the disease was selected. The blood from each of these individuals was obtained every day for seven days. In several cases the blood was tested against seven different hemolytic systems, and in every case the seven specimens were kept until the end of the period and then tested against a single hemolytic system. The results when daily tests were made were variable within narrow limits but very minute. Nineteen other cases showed either an absolutely constant titer for each specimen or a variation which was decidedly within the limits of mechanical accuracy. The tendency of salvarsan to bring out a positive reaction is well shown by a comparison of the cases Haller reports; and they bear out the statement of Swift that the early cases are more quickly rendered negative by mercury than the older ones. An attempt has been made by Haller to determine how long it is necessary to wait after treatment with mercury before any dependence can be placed on a negative test, and also to determine how much mercury is necessary to convert a reaction to a temporarily negative one. After following a fairly large number of cases for more than a year, doing their Wassermann reactions repeatedly, the conclusion was reached that the individual variation in cases is so great that rules of only doubtful value can be established and no hard and fast statements can be made. He concludes that the variations from month to month in the degree of positiveness of serums in cases of untreated syphilis are slight. The fixing unit for the serums in cases of untreated syphilis does not vary ap-

preciably from day to day; and that any variation found in daily titration for the fixing unit is due, provided the antigen is constant, to variation in the hemolytic system. On the majority of positive Wassermann reactions mercury has a prompt and powerful though fleeting action. Haller and his co-workers cannot agree with the statement that mercury is of little value in the treatment of syphilis.

16. Extragenital Syphilitic Infection.—William W. Cadbury reports the following unusual case, and calls attention to the fact that many cases of syphilis arise from extragenital infections of which the patient is wholly innocent as well as ignorant until some late manifestation of the disease appears. A physician, Celtic, aged 29, whose parents were living, in good health, and who had two brothers and one sister, all in good health, had measles as a child but otherwise no illness. No history of any venereal infection. Patient was married in 1910, and the wife, aged 29, had five brothers and sisters, as well as both parents, all living and well. She had had no serious illness and no history of venereal infection. A healthy child was born in 1911. In the spring of 1912, while engaged in an active surgical practice, the patient developed what he and a consultant supposed to be a felon of his finger. The sore healed after about six months' local treatment. The following fall an epidemic of dengue occurred in the physician's town, and he believed he had an attack. He suffered for several days with pains in the bones and joints, and had an eruption over the body resembling that usually seen in dengue. Later he suffered from insomnia and lost in weight. His wife had been perfectly well during the entire course of her husband's illness. In November, 1912, in the eighth month of pregnancy, her older child kicked her in the abdomen, and from then all sensation of quickening ceased and ten days later a macerated fetus was born. Death was attributed to injury. In 1913 she noted some tendency to alopecia, which was transient. In October, 1914, a healthy male infant was born at term. The labor was uncomplicated and the child perfectly normal apparently. In the fifth week the child was brought to the hospital for a cold in the head of several days' duration. Examination showed the infant to be moribund. There was a scaly eruption about the finger nails, and liver and spleen were enormously enlarged. After five hours the child died. Necropsy was partially performed and sections of the liver and spleen taken, which showed spirochetes in both organs. The father denied any venereal infection. Examination showed the scar on the finger from the felon and the postcervical glands were enlarged. Wassermann tests were made then on the patient, his wife, and oldest child. Those of the parents were both positive, but that of the child, evidently born before infection in 1911, was absolutely negative. A vigorous course of treatment with salvarsan was immediately instituted in both parents, in which the serum reaction ultimately became negative.

5. **The Treatment of Septic Wounds with the Simpson Light.**—J. A. Menzies states that after the use of the Simpson light for over seven months he considers that a report of his favorable results opportune at this time. He has seen great improvement following such treatment in three cases of lupus; one case of 18 years' standing was entirely healed, and two cases of advanced Graves' disease, in which the thyroid gland became smaller and the signs and symptoms decreased. He cites also the results on cases of wounds of the elbow, thigh, knee-joint, and leg in soldiers which were cured. Over forty cases were treated. The dose given was two and a half to three minutes at each sitting, and there were usually two sittings per week. The following may be regarded as among the distinctive features of Simpson light treatment: 1. The relief of pain, which often followed on the day after the first application. 2. The increase of movement, also following shortly after the first treatment, but does not apply to wounded joints. 3. The relief of swelling, tenderness, and inflammatory induration markedly reduced. 4. Absorption of scar tissue; this was shown by the results on old scars on the cornea, which cleared up. 5. Improved appearance in wound tissue, in which unhealthy granulation tissue became healthy. 6. Diminished discharge from the wound, a very marked feature.

7. **Observations on the Etiology of Sarcoma in the Rat.**—Albert S. Leyton and Helen G. Leyton offer the results of their experiments in the department of pathology of the University of Leeds on this subject. Some previous work on the hemolytic properties of the serum of rats inoculated with sarcoma showed them that these properties were to be found also in diseases of bacterial origin, and they proceeded to investigate into the possibility of a bacterial origin for sarcoma. They argued that the site of infection would probably be the cell nucleus, since most of the characteristics of malignant growth point to irritation of the nucleus. Rat sarcoma was made into an emulsion and filtered through a Chamberland filter. The filtrate was plated and a streptothrix isolated in several cases. They have also isolated a streptothrix from mouse carcinoma. They concluded that the streptothrix would hardly be a filter passer, but that the spores of the streptothrix had been filtered. A spore, too, might more easily enter the cell nucleus and also reproduce the streptothrix, either directly or through an alternate generation. They accordingly inoculated three rats in the axilla with 1 c.c. each of the sarcoma filtrate, which should contain the virus of the new growth. Tumors developed at the site of inoculation. They mention the fact that while several sarcomata have a filterable virus, it has not been mentioned in connection with the Ehrlich rat sarcoma. In order to test the relationship of the streptothrix to the formation of sarcoma, it was injected several times into the subcutaneous tissue and into the peritoneal cavity of rats, and several were fed with it weekly for some time. So far a tumor has resulted in one of the fed rats only, and it has all the characters of a spindle-cell sarcoma and is inoculable; from it the streptothrix has been isolated again. The streptothrix in question appears to be either very pleomorphic or several species are to be found in rat sarcoma. They also isolated one by the same method from the washings of the hair of a sarcomatous rat, but not, so far, from that of a normal rat.

2. **Remarks on Delayed Tetanus.**—Gilbert Barling reports three cases of this condition seen at the Second Birmingham War Hospital in which the tetanus developed in the first case after an incubation of fifty-one days, in the second after fifty-three days, and in the third after forty days, which was followed by gas gangrene seventy-three days after injury and forty-two days after the wound had healed. The first and second cases were given 37,500 units and 153,000 units of anti-tetanic serum in divided doses respectively. It is not known whether the third case received a prophylactic dose of serum. This man died about three months after he had received his wound. At the post-mortem examination cultures were made from the spleen and from the gangrenous area near the right shoulder. The former yielded the streptococcus and the latter an anaërobic bacillus in addition to the streptococcus. The bacillus was recognized as *B. perfringens* or *B. aërogenes capsulatus*. Barling's impression is that the *B. perfringens* was activated by the association with it of a streptococcus in a subject exhausted by a severe attack of tetanus. The occurrence of gas gangrene seventy-three days after the infliction of a wound and forty-two days after the wound had healed appears to be unique, and detailed search brought forth no other such case in current literature. With regard to the effect of the serum, Barling wonders whether a prophylactic dose may delay the onset of tetanus by directly influencing the growth of the infective organism and so reduce its virulence that it only shows its clinical effect under some special condition favoring more vigorous growth. Or, alternately, does the antitoxin thus given neutralize the first-formed toxin and so prevent the development of clinical symptoms, despite the growth of the infection, until all the antitoxin has been saturated? He cites several other cases in which a latent organism once active has been made active again as a consequence of injury and the resulting lowered resistance of the patient.

4. **Visual Neuroses of Miners in Their Relation to Military Service.**—Charles F. Harford records some of the cases of so-called miner's nystagmus which have been met with recently among miners coming from some of the counties of England who have found their way into the army. He considers the name miner's nystagmus to be unfortunate, as the nystagmus is only one symptom out of a group which may be absent even when the disease is present in a marked form. He enumerates the other symptoms that may be found, as follows: Defect of vision, hypermetropia, myopia, and astigmatism. But in no case was any abnormality of the fundus detected, temporary giddiness occurring often in the early morning; photophobia, or intolerance of light, was present in practically every case; headache, especially through the temples, either at night or in the early morning; perverted visual impressions, such as dancing lights or glittering lights, occurred with the nystagmus; the mental factor, shown by great mental depression, accompanied the majority of these cases; the nystagmus was not present in those cases in which the men had been above ground for a length of time, showing that the circumstances under which these men had been living was a factor in the development of this condition. There is no doubt but that it is a serious mistake for men who have any tendency to this complaint to be subjected to the arduous strain of military service, which places such tremendous demand on all the powers of mind and body, particularly of the eyesight.

Disturbances of Voice and Speech in the War.—

Gutzmann asserts that these are of much more frequent occurrence than is commonly believed. They accumulated to such an extent even early in 1915 that they formed a special class for treatment. A ward of 24 beds soon filled up and it was necessary to provide a special hospital division. At the present time 50 hospital and 20 dispensary cases are under treatment. There was great need of trained assistants, such as deaf and dumb instructors, but with one exception all the original lady volunteers deserted and she was the wife of one of the medical men. Later, deaf and dumb teachers came and remained steadfast. The author now proceeds to answer his own question, "How do soldiers come by these disorders?" The answer is "through injury or through illness." Mild transient cases of aphonia and aphasia follow fright and shock, but these are not considered in any connection. More serious and protracted conditions are caused by wounds of the organs of speech and injuries to the head. These need not detain us. Serious disturbances, however, are produced by wounds of remote localities and are not necessarily psychogenic. The shock of the wound may cause prolonged unconsciousness from which patient emerges speechless or voiceless. Physical shock must be invoked to explain such cases. A reflex cause could be excluded. The disturbances in question comprised aphasia, phonastema, dysarthria including the spastic form, and kinetoses of all kinds, very often accompanied with exhaustive states. Treatment was for the most part imperfectly successful with occasional good results. One soldier upon recovering from shock after protracted unconsciousness showed total aphasia. As this passed off dysarthria and dysphasia were left and persisted for eight months. After this bradylalia was the only symptom in evidence. Thirteen months expired before he could resume his duties as officer. The author writes at great length on the various forms of speech disturbances encountered, including stuttering, and preserved a number of phonographic records for demonstration.

War Literature of Internal Medicine.—Reckzsch continues his review of this subject and mentions the literature of army rheumatism. One-third of these cases consist of polyarthritis acuta, which as a rule were mild and in almost all instances due to sojourn in damp trenches. Certain cases, however, could be attributed to an angina. Diarrhea was not infrequently a prodrome. The joints of the lower extremities were most frequently attacked. No distinction could be made between neuralgias and myalgias. Chronic affections of the joints have a marked static factor and demand orthopedic correction. One writer finds that in chronic rheumatism so-called muscular affections predominate. There is often extreme tenderness over the tendons, muscular insertions and periosteum. Drugs have little influence on chronic rheumatism of any type. Perhaps, in contrast to the general opinion, the German psyche has shown a high degree of resisting power to the psychic insults of warfare. This find proved a welcome surprise to the Germans themselves. Psychoses are few in number. Neurasthenia, while common and severe, responds rapidly to treatment.

Münchener medizinische Wochenschrift.

February 15, 1916.

Peculiar Late Exanthems After Inoculation Against Cholera and Typhoid.—Friboes refers to a series of 10 or 12 cases of soldiers admitted to a clinic with apparent scarlatina. Inspection showed, however, that the

latter could be readily excluded. The exanthem appeared to be quite unknown and could only be interpreted as a late result of immunisation,—as afterward appeared some three or four weeks after the injections. A second batch of nine cases was received at a later period and here a complete history was obtained. Despite notable points of difference the rash could readily pass for atypical scarlet fever, which would lead to unnecessary isolation. The eruption may show considerable diversity, especially in mild cases and early stages. The well developed case is confusing, because despite dissimilarities in the rash there may be associated with the latter vomiting, fever. The buccal phenomena of scarlatina may be present, such as the strawberry tongue; and while the angina is of a mild, diffuse type, in one case there was ulceration and otitis media. Conjunctivitis, coryza, and bronchitis were more or less in evidence. Enlarged cervical glands were absent. The most striking property of the exanthem is a slightly yellowish tint such as has never been observed in scarlatina. The affection appears to be quite new in medicine and its relation to inoculation is obscure; typhoid immunizing bodies cannot of course be accused of provoking a specific rash because cholera vaccine produced a like result.

Dangers of Pyelography.—Professor Simmonds concludes his paper as follows: Not alone is collargol poisoning a possible danger, but there is a far more serious sequela encountered at times, to wit., septic infection. To guard against the latter the bladder and renal pelvis must be sterile when the injection is made, and all pains taken to prevent injury of the kidneys. In any death whatever which was preceded by a pyelography, blood tests should be made. To return to collargol, this substance has been pronounced nontoxic by authorities, i.e., no form of argyrimism has been described. Affections imputed to it—as acute hemorrhagic diathesis—may have been caused by sepsis, or, as happened in one case, by the anesthetic. A case of the author's is as follows: Man, aged 34, was submitted to pyelography because of the general vagueness of his symptoms. They were irrigated with 15 c.c. of 5 per cent. solution, and the operation caused a sense of pressure. At night the patient vomited and passed much bloody urine, followed by a hemorrhagic exanthem. Death took place on the third day. The autopsy showed the picture of hemorrhagic sepsis. There was evidence that the kidney pelvis had been directly injured, while both kidneys were the seat of a diffuse process (anuria had succeeded hematuria). All doubt as to the nature of the disease, Simmonds said, vanished after hemolytic streptococci had been cultivated from the blood.

Paratyphoid Fever in the Tropics.—Professor Castellani says that paratyphoid is a milder and shorter disease than true typhoid, of course, with exceptions. In the Tropics the two conditions cannot be differentiated clinically, as true typhoid often runs a most atypical course and may begin quite abruptly. The diagnosis, therefore, is based on bacteriological findings. His treatment is the same as for true typhoid, and he adheres to the older treatment of strict fluid diet during the whole course of the fever, and for some days after its subsidence. The newer method of treatment by a more substantial diet had been tried, but the mortality had been much greater than on the fluid diet, and as the cases in both Ceylon and India often show a malignant type, a return had been made to the old treatment. Prophylaxis is to be found in anti-paratyphoid inoculation.—*Proceedings of the Royal Society of Medicine.*

Book Reviews.

THE PRACTICAL MEDICINE SERIES, comprising ten volumes on the year's progress in medicine and surgery, under the general editorial charge of CHARLES L. MIX, A.M., M.D., Professor of Physical Diagnosis in the Northwestern University Medical School, Chicago: The Year Book Publishers, 1915.

Volume I. GENERAL MEDICINE. Edited by FRANK BILLINGS, M.S., M.D., Head of the Medical Department, and Dean of the Faculty of Rush Medical College, Chicago, and J. H. SALISBURY, A.M., M.D., Professor of Medicine, Illinois Post-Graduate Medical School. Price, \$1.50. This volume deals with such infectious diseases as tuberculosis, pneumonia, poliomyelitis, smallpox, rheumatism, and pellagra; likewise the diseases of the lungs, heart, arteries, blood and blood-making organs, ductless glands and kidneys, and the metabolic diseases. The book gives one an opportunity to review the progress made in the diagnosis and treatment of these diseases.

Volume II. GENERAL SURGERY, edited by JOHN B. MURPHY, A.M., M.D., LL.D., F.R.C.S. England (Hon.), F.A.C.S., Professor of Surgery in the Northwestern University; Attending Surgeon and Chief of Staff of the Mercy Hospital and Columbus Hospital; Consulting Surgeon to Cook County Hospital and Alexian Brothers Hospital, Chicago. Price, \$2.00. This volume contains abstracts of the literature covering pretty thoroughly the whole realm of general surgery. Where indicated, comments have been made by the editor, and this enhances the value of the book.

Volume III. THE EYE, EAR, NOSE AND THROAT, edited by CASEY A. WOOD, C.M., M.D., D.C.L.; ALBERT H. ANDREWS, M.D.; WILLIAM L. BALLENGER, M.D. Price, \$1.50. This volume contains abstracts of a great many interesting papers. Thus it proves valuable for a quick review and study, to both the specialist and the general practitioner.

Volume IV. GYNECOLOGY, edited by EMILIUS C. DUDLEY, A.M., M.D., Professor of Gynecology, Northwestern University Medical School; Gynecologist to St. Luke's and Wesley Hospitals, Chicago, and HERBERT M. STOWE, M.D., Assistant Professor of Obstetrics, Northwestern University Medical School; Attending Gynecologist to Cook County Hospital. Price, \$1.35. The author discusses in order general principles, disorders of menstruation, displacements and injuries, infectious and allied disorders, malformation and tumors, and sterility.

Volume V. PEDIATRICS, edited by ISAAC A. ABT, M.D., Professor of Pediatrics, Northwestern University Medical School, Attending Physician Michael Reese Hospital. ORTHOPEDIC SURGERY, edited by JOHN RIDLON, A.M., M.D., Professor of Orthopedic Surgery, Northwestern University Medical School, with the collaboration of CHARLES A. PARKER, M.D. Price, \$1.35. Although there has been no particular advance made in either pediatrics or orthopedics, the many interesting cases recorded in the literature of the past year furnish material for a very instructive volume.

Volume VI. GENERAL MEDICINE, edited by FRANK BILLINGS, M.S., M.D., Head of the Medical Department, and Dean of the Faculty of Rush Medical College, Chicago, and J. H. SALISBURY, A.M., M.D., Professor of Medicine, Illinois Post-Graduate Medical School. Price, \$1.50. In this book the editors treat of the infectious diseases not considered in Volume 1 of the series, and the diseases of the gastrointestinal tract. Many instructive cases are recorded and newer methods of diagnosis and treatment discussed. A very helpful book is the result.

Volume VII. OBSTETRICS, edited by JOSEPH B. DE LEE, A.M., M.D., Professor of Obstetrics, Northwestern University Medical School, with the collaboration of HERBERT M. STOWE, M.D. Price, \$1.35. The editor divides the book into four parts, namely, pregnancy, labor, puerperium, and the new-born. In the part devoted to labor are a number of articles dealing with twilight sleep, with a summary by the editor. A perusal of these articles convinces one that the method should be employed only by the specialist in obstetrics, and then only if the patient is cared for in a well-equipped maternity hospital, having a thoroughly competent staff. Even then one is not sure that the treatment is desirable. There are many other interesting articles which add greatly to the practical value of this volume.

COLON HYGIENE. Comprising New and Important Facts Concerning the Physiology of the Colon and an Account of Practical and Successful Methods of Combating Intestinal Inactivity and Toxemia. J. H. KELLOGG, M.D., LL.D., Superintendent of the Battle Creek Sanitarium; Author of "Neurasthenia, Its Causes and Cure," "Rational Hydrotherapy," "The Art of Massage," "Light Therapeutics," etc. Price, \$1.75. Battle Creek, Michigan: Good Health Publishing Co., 1915.

THIS book covers in a thoroughly sensible and reasonable manner the physiology and therapeutics of the intestinal tract, especially that of the colon. It is written in a semi-popular style, which, while in no way detracting from the benefit to be derived by the physician, places it within the scope of the intelligent, nonmedical reader. The reader is asked in the preface to note especially that no panacea is offered for colon miseries; there is no "cure all" for constipation. The way out of the slough of intestinal toxemia with its "biliousness," headaches, neurasthenias, and multitudinous maladies is to be found only through living biologically, and making use of the "safe and sane" helps which recent scientific progress has provided. The purpose of the work is rather to enable the patient who may read it to cooperate intelligently with the wise up-to-date physician. Besides complete descriptions of exercises for the treatment of constipation, baths, and electrical methods, a diet is given, containing valuable recipes for the preparation of some of the foods.

A TEXT BOOK OF PHYSIOLOGY FOR MEDICAL STUDENTS AND PRACTITIONERS. BY WILLIAM H. HOWELL, Ph.D., M.D., Sc.D., LL.D., Professor of Physiology in the Johns Hopkins University, Baltimore. Sixth edition, thoroughly revised. Price \$4.00. Philadelphia and London: W. B. Saunders Company, 1915.

FOR those who are already familiar with Professor Howell's book, the news that a fresh edition has appeared will be both interesting and agreeable, while for the benefit of those who do not know the work it may be stated that the event is truly one of importance. Physiological science has become so complex and its problems ramify in so many directions that it is almost impossible for a single mind to have authoritative command of the entire subject. Yet the advantages of the one-man book when it is well done are so great that for the ordinary reader it is to be preferred to the collaborative works produced by a group of contributors, which are so very popular and numerous in Germany. However well edited such a treatise may be, it must inevitably suffer to some extent from its patchwork character—there are always gaps and duplications, and often conflicting points of view—while a book from a single but competent pen often makes up by its greater coherence and continuity of thought for any possible shortcomings in special fields. The present volume is a shining example of how good such a book may be, when it is the work of a master, and it is a pleasant task to call attention to its appearance in a sixth edition. Much new matter has been added, especially in the section on nutrition and that in the internal secretions, which latter forms a most comprehensive summary of what is known and what is believed in this very mysterious field. It is altogether a valuable and important book which thoroughly deserves its popularity with teachers, students, and general readers.

A TEXT BOOK OF THE PRACTICE OF MEDICINE. By JAMES M. ANDERS, M.D., Ph.D., LL.D., Professor of Medicine and Clinical Medicine, Medico-Chirurgical College, Philadelphia. Twelfth Edition, Thoroughly Revised. Octavo of 1336 pages, fully illustrated. Price, cloth, \$5.50 net. Philadelphia and London: W. B. Saunders Company, 1915.

WHEN a medical work reaches its twelfth edition there is little left to tell about the contents except that the book has been brought thoroughly up to date in every branch of the practice of medicine. In this book new sections have been added on Colon Bacillus Infections; Tuberculosis of the Thyroid Gland, and Hypophyseal obesity. Also a rewriting and addition of Acute Anterior Poliomyelitis; Rôle of the Cockroach in Spread of Cholera; Glycyltryptophan Reaction in Cerebrospinal Meningitis; Neosalvarsan; d'Espiné's Sign in Tuberculosis of the Bronchial Lymphglands, and Bárány and Neumanns' Test in Diagnosis of Labyrinthine Disease. Dr. Anders' work has stood out prominently for the past eighteen years in a field of medicine, the literature of which has vastly increased in that length of time.

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held February 17, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

THE President announced that the subject of the evening would be "Saratoga Springs." New York State had purchased and restored the mineral springs of Saratoga. Through a Commission it was maintaining and administering them in the interests of the people.

What the State Has Done at Saratoga.—GEORGE FOSTER PEABODY, Esq., formerly chairman of the Saratoga Commission, said that the State had accomplished a great deal at Saratoga but he could make only a short report because of the time limit. There was one great thing that the State had done in connection with the work at Saratoga Springs: it had obtained the aid of experts and the men of science had produced an element of faith. As was well known, some people were inclined to lose their faith in the waters but now the science of medicine had demonstrated the power of faith. The citizens of the State, as well as those of Saratoga Springs, had been given much knowledge which showed them the natural value of the resources located there. The history of the Springs was such a long one that Mr. Peabody said he could not enter into a full account of it. He wished to call attention to the fact that there was a great profit to be had from the sale of the waters; the mineral springs at Saratoga, which have been taken over by the State, were fully as potent in medicinal value as those abroad, but it was necessary to acquaint physicians throughout the country with the curative value of the springs. The reputation of the springs had been much impaired by the commercial exploitation of the gas. When the springs were nearly ruined then the matter was up to the citizens of Saratoga Springs and to the Legislature. Under the leadership of Senator Brackett a bill was finally presented and passed appointing a Commission to look into the matter and to report. This Commission spent a great deal of time in gaining information and recommended the purchase by condemnation to rescue this great reservation for the State. Finally a bill was signed by Governor Hughes endorsing the action taken. The property was acquired gradually by the State. But there were some people who did not believe that the waters could be recovered; they were very skeptical. After the Commission had made a careful study and learned certain facts, it was warranted in having this faith strengthened and it felt that it could go forth and take some risks. At this time the Commission was fortunate in having the advice of Dr. Simon Baruch, a member of the New York Academy of Medicine, who was in London at that time. Without compensation Dr. Baruch devoted months of his time in making observations at the European spas and he brought the Commission, as it proved to be, a complete guide to the building up of Saratoga as a cure. Not less important was it that Dr. Baruch took a broadminded view of the situation and in a public spirited manner gave them his observations, particularly as to the conditions in Kissingen and Nauheim, the waters of which resembled those of Saratoga Springs. At Kissingen he met Dr. Paul Haertl, who was in charge of the Royal Laboratory. Finding him an exceptionally able man in all matters appertaining to mineral springs, Dr. Baruch immediately secured his services subject, of course, to the approval of the Commission. The latter accepted Dr. Baruch's advice and obtained from the United States authorities permission from the Royal Bavarian Government to invite Dr. Haertl to Saratoga Springs. He found that some of the waters had been ignorantly exploited. It seemed to be a clear case of "killing the goose that laid the golden egg." The reputation of the cure abroad was based on a long knowledge and expression by physicians of the helpful qualities of the waters there. So far as Mr. Peabody had been able to discover, the confidence of the physicians in this country regarding the beneficial qualities of these waters needed to be assisted almost as much as that of the patients. The physicians abroad believed in the value of the springs there, but American physicians seemed to show more faith in the springs abroad because they had not until now been properly investigated. The Commission had been able to demonstrate

that the springs would recover their mineral content. The quantity of CO₂ now demonstrated to be available seemed to be sufficient to warrant the belief that the springs at Saratoga would come back, and with full power. The State should be aroused to the necessity of having proper buildings and proper environment, for the Commission had had a very limited amount of money at its disposal. The fact that there were so many fine trees, pine growths and a great variety of tree growths in the Adirondacks, at the foothills of which Saratoga lay, should make the basis for an attractive resort. About \$1,500,000 were needed for the acquisition of properties, for repairing damages of retubing, etc. The bulk of this money, however, was spent for acquiring properties necessary. At the present time there was only one bathhouse open during the winter and hotel accommodations were badly needed during the winter at the springs. Just at this time when patients could not be sent abroad on account of the war, the State should make the best possible provision for those at Saratoga Springs. It was too bad that there was such a lack of hotel accommodations during the winter. Only one spring was run during the winter, but some could get places at boarding houses. The State of New York would certainly be doing a great service in conserving the waters at Saratoga Springs now. The cost of what was necessary to effect these changes should be properly placed before the people of the State. Mr. Peabody said he had been particularly impressed among the business people he had been associated with, by the number of those who had heart troubles, and it seemed to him that in this city of New York, where the stress of life was so very strenuous and severe, it was very important to have a place where this class of patients could be conveniently sent, such as Saratoga Springs, with its climatic advantages and other attractions. This would be an enormous economic advantage for these men of large affairs, because they could take the cures in this country without the danger and risk of an ocean voyage.

The Springs of Saratoga; Their Value in the Treatment of Disease.—Dr. W. GILMAN THOMPSON presented this paper. (See page 589.)

The Geology of the Saratoga District, and the Source of the Mineral Waters.—Dr. ALBERT WARREN FERRIS delivered an extemporaneous address, describing the stratified rock of the Saratoga quadrangle, the change of the topography caused by the oscillations of the earth's crust, and the action of the ice sheet, as well as the pores, bedding planes and solution channels existing in dolomites, limestones and sandstones. He outlined the theories of the origin of the mineral water and explained the solution of various minerals in the water, the presence of the gas and the foreign chemistry of the mineral constituents. His talk was illustrated with colored lantern slides showing features of Saratoga Springs as a health resort, some examples of the work of the State Reservation, and the famous High Rock Cone first seen by a white man in 1643, when Father Isaac Jogues was taken prisoner by the Mohawks and brought down from the Algonquin country to the flowing springs of the Kayaderossearas country.

Stated Meeting, Held March 2, 1916.

VICE-PRESIDENT, DR. EDWARD D. FISHER, IN THE CHAIR.

THE program was arranged by the Sections on Medicine and Surgery. The subject for the evening was "The Importance of the Early Recognition of Cancer of the Stomach for the Purpose of More Frequently Obtaining Successful Surgical Treatment."

The Reasons for Early Diagnosis of Cancer of the Stomach.—Dr. CHARLES H. PECK told of their experience at the Roosevelt Hospital during the past six years. The statistics showed that in the year 1913 there were 75,000 deaths from cancer in the United States, and that of this number 30,000, or about 38 per cent., were due to gastric carcinoma. The stomach was more frequently attacked than any other organ. The disease was more common in males than in females. Smithers in a series of 921 cases proven by operations or autopsy, found a proportion of 3.04 males to 1 female. In their own series of 95 cases, there were 71 males and 24 females, slightly less than 3 to 1. Since January 1, 1910, they had had under treatment in the surgical wards of Roosevelt Hospital 95 cases of gastric carcinoma, 71 of which were verified by operation. The remaining 24

were either inoperable when admitted (18) or refused operation (6). Of the 71 operations, 26 were simple explorations, the advanced stage of the disease or metastatic deposits prohibiting further operative interference; 18 had secondary deposits in the lymph nodes, pancreas, liver, peritoneum or colon; 2 were extensive growths without definite metastasis, and in 6 instances details were lacking. Eight of these cases died in the hospital following operation. Careful consideration of the extent of the disease made it possible to recognize more frequently inoperable types and fewer fruitless explorations would be performed in the future. Such operations brought no relief to the patient and no credit to the surgeon. This comment did not apply to exploration in the early or doubtful cases. In 21 cases palliative gastroenterostomy was performed; 5 died in the hospital and 16 were temporarily benefited. Some of their failures could be charged to ill-advised surgery in advanced cases without definite pyloric obstruction. Secondary deposits were present in the lymph nodes in 14 of these cases, in the liver in 1, and the pancreas in 2. Of the 71 operations performed, therefore, 55, or 77 per cent. were exploratory or palliative, and only 16 were radical excisions of the growth. The education of the public and the profession in regard to the prevalence and dangers of gastric cancer, the difficulty of distinguishing its early stages from benign conditions, and the promise of early improved results from surgical treatment if cases could be operated upon in the early stages, offered their best hope of improving results. Two of his own cases not included in this series were alive and well after radical operation for what was believed to be at the time benign callous ulcers but in which the microscopical examination showed early carcinoma. If one could consider every callous ulcer successfully excised as potential carcinoma, then indeed they could take heart and feel that some progress was being made in the battle against this disease. Wide differences of opinion still existed as to the frequency with which benign ulcer actually developed into carcinoma. In 61 cases of their series in which the duration of symptoms was not recorded, only 12, or 20 per cent., gave a history of long preceding chronic dyspepsia, the time varying from 3 to 15 years. Eight cases had symptoms from one to two years; 12 from six months to a year; 13 from three to six months, and nine for three months or less. If any inference was to be drawn from these figures it would be that many of the cases developed carcinoma without a preceding ulcer history. Sixteen cases were treated by partial gastrectomy with five deaths, an operative mortality of 31.3 per cent. Few of this group could be called examples of the early stages of the disease; many had large ulcer growths, nine of the 16 having definite lymph node metastasis at the time of operation, and two being adherent to the pancreas. Of the 11 cases which recovered from the operation, two lived three years and two and a half years respectively; two sixteen months and one fifteen months and finally died of recurrence. Where the growth was movable and partial gastrectomy was possible, the operation was quite worth while. In this brief résumé of their experience the cases diagnosed or presented for surgical treatment early had been a rarity. The material analyzed had consisted of cases so advanced that palliative results alone could be hoped for in the majority of the cases. Among the many reasons why the disease was so often far advanced when first seen by the surgeon were the following: (1) Failure on the part of the patient to seek advice through inattention to early symptoms, fear of an unfavorable prognosis or other reasons; (2) disregard of advice, through lack of confidence, fear of operations, or meddling interference of friends; (3) ill-advised prolongation of medical treatment for supposed dyspepsia or ulcer; (4) insidious onset and rapid progress of the disease in a certain percentage of the cases. With the modern diagnostic means at their disposal much delay could be saved and many more cases could reach the surgeon in an operable and curative stage than had been the case in the past. The idea that gastric carcinoma was essentially hopeless from the beginning should be combated, for in the early stages it was favorably situated for wide excision and lymph node involvement and metastatic deposits were in many cases of late occurrence.

Methods by Which Early Diagnosis of Gastric Cancer May Be Made.—Dr. THOMAS McCRAE of Philadelphia, in considering this phase of the subject, said that the question of the early diagnosis of gastric carcinoma was one of the most difficult problems of medicine and

there were many reasons why this was so. Gastric carcinoma might give no symptoms until it reached a comparatively advanced stage, gastric complaints were common, and the early symptoms of carcinoma sometimes responded so readily to the same methods of treatment that were effective in these trivial disorders that people were lulled to a sense of security. As regarded the history, Dr. McCrae said that in medical clinics only in a small proportion of cases did gastric carcinoma seem to be engrafted on chronic ulcer. In 150 cases reported by Osler and McCrae, only thirty-three gave a history of any previous gastric disturbance, and in a control series selected from patients with other diseases there was practically an equal incidence of history of gastric symptoms. Dr. Friedenwald reported 1000 cases, among which only 23 per cent. gave a history of previous gastric disturbance. This seemed to be the general experience of medical clinics. In two groups the history was suggestive, the one in which it developed on gastric ulcer and the other in which the symptoms began suddenly. One point to be emphasized was that a diagnosis could not be made on any one sign or symptom alone. As regarded the examination, the internist must spend sufficient time in the study of a case to reach a diagnosis. The general physical examination usually gave very little help in reaching an early diagnosis. The study of the gastric contents should be done by the continuous method throughout the whole course of digestion. In speaking of the various tests of the stomach contents, Dr. McCrae said he felt that the simpler things offered the best chance of reaching a correct diagnosis for most physicians. The finding of pus cells and blood in the empty stomach and again two hours after the meal was important. As to the secretions, a definite drop in the curve of acidity, as though the stomach had become exhausted or as though something had inhibited the secretion, might excite suspicion. The finding of pus, blood, and some mucus two hours after a test meal was important evidence. The study of removed material for tissue fragments, although laborious, was sometimes a means of making a definite diagnosis. In speaking of some of the other tests of the gastric secretion, Dr. McCrae referred briefly to the tryptophan and glycytryptophan tests. These were not pathognomonic and their value was doubtful. The work of Hawk, Rehfuess, and their associates showed that the trypsin enzyme was almost constantly present in the stomach. If that was so it took away the value of these tests. This work showed that the trypsin enzyme was very resistant to the action of acid and pepsin, and that the tryptic value was high when the acidity was low or when there was anacidity. The same applied to the formal index, the test for erepsin. The test for soluble albumin was regarded very differently by different observers, but might be of more value at the end of two hours than at the end of one hour. Another point with reference to the study of the protein curve through the process of digestion was a divergence of the protein curve from the acid curve, which became more marked as digestion proceeded. There were a number of other tests more or less difficult to do and more or less disappointing. One point to be emphasized was that simple methods persistently carried out gave information of great value and, though not one of the tests alone was pathognomonic, if a number of them agreed the evidence might be depended upon. With reference to the value of the x-rays, perhaps a clinician was not qualified to speak; but in growths about the middle of the stomach there was a more or less constant deformity into the lumen of the stomach. If the growth was at the pylorus it was often annular, and one found a more or less permanent condition and the permanence of this condition was important. Sometimes we must decide whether a laparotomy should be done for diagnosis rather than try to make a positive diagnosis of carcinoma. If there was a reasonable doubt as to the diagnosis, an exploratory operation was a method which one should not hesitate to employ.

Dr. GEORGE D. STEWART said that he did not believe that he could add much to the exhaustive study of the subject that had been presented; he could merely reaffirm what had been stated or affirm what he believed. They were all agreed that gastric carcinoma, like all other carcinomas, had a stage during which it was a localized disease. Hence the making of an early diagnosis during the stage of localization was of the greatest importance. Too frequently, however, the onset of symptoms in cases of gastric carcinoma was very sudden, there being few or no preliminary symptoms to

give warning of the presence of cancer. That 71 per cent. of the cases of gastric carcinoma began in gastric ulcer he thought was overstating the matter. Because young men liked rules and because a well-stated rule was of great service as a guide, even if experience brought many exceptions, Dr. Stewart said he would repeat a rule. In Patterson's work on the surgery of the stomach the author argued in favor of an early exploratory operation in cases in which one could not make an accurate diagnosis. He asked, "When should one perform an exploratory operation?" and replied, "When the probability of cancer has been established." To the further question, "When has the probability of cancer been established?" he answered, "When a patient in or past middle life suffers from progressive gastric disease which does not yield to treatment and also exhibits any two of the following symptoms: First, absence of free hydrochloric acid and impaired digestive power; second, marked diminution of protein hydrochloric acid; third, constant presence of blood in the feces, macroscopically or occult; fourth, gastric stasis and impaired motility; fifth, abnormal excretion of uric acid." Like all of the rules, there were certain exceptions; but it seemed to Dr. Stewart that this was a fairly good guide. After all, it was, as Dr. McCrae had stated, frequently not a question of determining whether a cancer was present or not, but of determining whether or not there was a condition in abdomen or stomach which demanded operative interference.

Dr. ADRIAN V. S. LAMBERT said that from the standpoint of the surgeon there might be some extenuation of the position of which Dr. McCrae spoke when he stated that the surgeon held that the internist did not take full histories. This was probably because by the time the surgeon saw the case there was a definite history, and then he wondered why the internist had not made an earlier diagnosis. At the present time there was no fair criterion by which one could say that cancer was present. It seemed as though we were waiting for cancer to declare itself instead of reaching out to the allied conditions with symptoms that pointed to cancer. At present it was interesting to observe the number of conditions for which patients were treated who subsequently came to be treated for carcinoma. A severe anemia of unknown origin and not benefited by proper dietetic measures occurred with sufficient frequency in connection with carcinoma to suggest the possibility of carcinoma. Patients had come under his observation who had had such anemias for from six to eighteen months and had been treated more than once for the anemia, and yet not one had had a gastric analysis made. With a knowledge of the allied conditions that might lead to the development of cancer, and with heed to an anemia of unknown origin and resistant to treatment, we should have taken a step toward the early diagnosis of carcinoma of the stomach. Dr. Lambert said that he did not believe that the history of ulcer established the diagnosis of gastric carcinoma. This seemed to be the experience of those who had treated ulcers. He did not believe any one was able to say when a carcinoma was engrafted on an ulcer. In view of the difficulties that surrounded the early diagnosis of gastric carcinoma, early removal of deforming ulcer of the stomach was indicated. It did not seem that they would ever be able to make an early diagnosis in cases in which the patient had no symptoms to indicate the presence of carcinoma. The x-ray was a very reliable method of telling whether the patient had a deforming ulcer or not.

Dr. GEORGE R. LOCKWOOD said that when a patient in whom there might be a bare suspicion of the possibility of cancer presented himself to the internist, the latter found himself in a serious predicament. If he waited for the development of definite symptoms before sending the patient to the surgeon, when he finally did send him it might be too late; he had only one other alternative, and that was to send the patient, as Cæsar sent his wife to the divorce court, on suspicion alone. It was sometimes helpful to formulate rules for the exclusion of non-malignant conditions. It was helpful to remember that a so-called chronic gastritis, aside from that form due to alcoholism, was more than a gastritis if accompanied by pain or vomiting. One could not depend upon the lack of hydrochloric acid as a sign of carcinoma of the stomach, since this lack was found in both malignant and benign conditions. Of the total achylia only a little over 3 per cent. were malignant cases; the remaining 97 per cent. were examples of the benign form. In the non-malignant achylia the mo-

tility of the stomach was good, but should stagnation of gastric contents coincide with the achylia one should suspect carcinoma. Many such cases were treated for neurosis. It seemed that if a patient had stood the stress and strain of life until reaching the age of forty-five years without a nervous break, the development of gastric symptoms at this age could not be ascribed to neurosis. As to a previous history of ulcer, Dr. Lockwood said that his figures were almost identical with those of Dr. McCrae; 13 per cent. of his cases gave a history of gastric symptoms, and gastric analyses had shown that in but 7 per cent. could the symptoms be ascribed to ulcer. So he could only reiterate that the most suspicious symptom of gastric carcinoma was the occurrence of gastric symptoms in individuals who had hitherto been free from such symptoms. The diagnosis between ulcer and carcinoma was often difficult. In case of doubt the patient should be treated by a rigid ulcer cure, such as the cure commonly spoken of as von Leube. If the symptoms resisted such a treatment for four weeks, or if at the end of that time occult blood was found in the stools, or if there was a progressive chloranemia, or if there was a loss of weight not accounted for by the limitation of diet, the case should not be considered one of uncomplicated ulcer, but justified that such case be referred to the surgeon.

Dr. JACOB KAUFMANN said that he frequently met with the erroneous conception that when a patient presented sufficient symptoms to give a positive diagnosis of carcinoma of the stomach he was already inoperable. This conception had produced an indifference that did not help in getting the patient to the surgeon. The term "early diagnosis" was vague; it was meant to convey the idea that the diagnosis be made at a time when a tumor was still removable. The operability of a growth, however, did not depend only on its duration, but much more on the character of the growth. A scirrhus might still be operable after a long period, while a soft tumor might be inoperable at an early date. Again, with improved methods of operation a tumor might be considered operable to-day which a short time ago would have been regarded as inoperable. We could reach a diagnosis more frequently if we avoided placing too much emphasis on the general picture and abstained from formulæ that were supposed to be applicable to all cases. There was a difference in the symptoms of cancer engrafted on ulcer and those of primary cancer; a difference between cancer of the pylorus producing obstruction and cancer in the middle portion of the stomach with a tendency to early anemia. If one were familiar with the idea that cancer presented different pictures the suspicion of its presence in any given instance would occur much more readily than if one had in his mind a more general picture of carcinoma. One was handicapped by that group of patients which showed a period of latency. But once the patient reported to the physician a diagnosis could usually be made, if only proper examinations were made. He regretted to say that the majority of cases that had come under his observation had been treated, often for many months, as nervous dyspepsia or gastric catarrh, without even an attempt at a more thorough examination having been made. An important point in the history of these cases was the abrupt onset of symptoms. When a patient reported that he had formerly enjoyed good health and now suddenly suffered from loss of appetite and loss of weight one's suspicions should be immediately aroused. The history was different in the cases of carcinoma engrafted on ulcer, which usually gave a history of a long period of suffering. In regard to the frequency of these cases, his experience had been the same as that of most medical men in that the percentage of ulcer cases that became cancerous was rather small, and, on the other hand, that primary carcinoma formed by far the majority of the cases. The question of cancerous transformation became of practical value in the ulcer cases which had become intractable to medical treatment and thereby had become subjects for operation. In such cases he gave the patient the benefit of the doubt in regard to cancerous degeneration and favored resection all the more, as this procedure was the only operation from which one could expect a cure of the ulcer. As to the value of the x-ray which at present claimed the center of the stage, there was no doubt that it was very valuable, but extravagant claims had been made that the x-ray alone could settle the diagnosis of carcinoma of the stomach. Dr. Kaufmann said he had a series of cases in which the diagnosis of cancer had been made by the x-ray and no cancer was present, and still worse were those cases

in which the *x*-ray had failed to make any diagnosis, particularly in infiltrating tumors. Schuetz of Vienna, in a series of 220 cases of cancer coming under his observation, had made the diagnosis in 196, or 88 per cent. in the majority of the cases before or without *x*-ray examination. In order to test the value of the *x*-ray he had 130 cases examined in the Institute of Holzknecht. All were examined by modern methods and 100 gave positive results, while thirty were negative or very uncertain. In twenty-six of the thirty cases in which the *x*-ray had failed to give the diagnosis it was made by physical or chemical methods. In sixteen of the 100 positive cases the *x*-ray settled an otherwise doubtful diagnosis. He personally had had such experiences and they certainly proved the great value of the *x*-ray. But the *x*-ray should not dominate at the cost of physical and chemical methods of examination as was the tendency at present. Dr. Kaufmann said he regretted that the time would not allow him to discuss the great importance of physical and chemical methods of examination.

Discussion on the Importance of the Early Recognition of Cancer of the Stomach, Etc.—Dr. WILLIAM V. HAYES said there were a few points in connection with this subject which would bear emphasis. One might have cases of carcinoma of the stomach with the free hydrochloric acid 78 and the total acidity over 100. In many cases one must not expect to find a diminution of the hydrochloric acid. Again many cases develop carcinoma without showing any cachexia. Where there was anemia without distinct cause it should arouse the suspicion of a malignant condition, but the fact that the patient did not show this sign did not exclude the possibility of cancer. Progressive loss in weight, steady diminution in the gastric acidity, the finding of occult blood which did not yield to treatment were suggestive of carcinoma of the stomach; nevertheless one would find himself very much deceived in some instances if he put his dependence entirely on these clinical methods without using the *x*-ray. The *x*-ray in the hands of a competent man gave more light on this condition than any other procedure. Unfortunately many radiographs were worthless, and herein lay the difficulty. Many live where it was impossible to have a good *x*-ray examination made, but where it was possible to get a competent radiologist the *x*-ray was the most valuable diagnostic measure available at the present time in reaching a correct diagnosis in suspected carcinoma of the stomach.

Dr. FENTON B. TURCK spoke in regard to the supposed origin of carcinoma in chronic gastric ulcer. He said the anemia preceding cancerous symptoms for some little time was no argument for a simple ulcerative cause of the carcinoma; it was merely an early symptom of malignancy. The experiments on animals to produce peptic ulcer showed that a primary induced anemia was quite as likely to be an underlying cause of gastric ulcer as the presence of an ulcer was likely to be the cause of a secondary anemia. After all we *did* know that carcinoma tended to ulcerate. We were not at all sure of the reverse process. Cases of gastric ulcer proved to have been such by operation had had recurrence of the symptoms with a cure by the internist; but the symptoms were those of ulcer as distinct from carcinoma. It seemed that the trend of opinion of this meeting agreed with the most recent authoritative literature, that in a very small percentage of cases could we feel sure that carcinoma formed on the basis of a chronic ulcer. The reasonable corollary of this should be that operation for pyloric ulcer, except in cases of perforation or obstruction, should not be considered the procedure of choice.

Dr. MAX EINHORN said that this subject had occupied the attention of the medical profession for twenty-five years and all were agreed that cancer should be operated upon as early as possible, and early diagnosis was the aim of every practitioner not only in cancer but in all other diseases. We could make a diagnosis of cancer of the stomach if we took into consideration the whole picture of the disease and not any one thing alone. If carcinoma developed to a sufficient extent to interfere with some function it might be detected, but if it was not that far advanced one could not discover it; it seemed that they must all accede to this limitation. All they could hope to do was to find it where it had already done something. Many patients called upon the physician with stomach trouble and the physician must do the best he could for the patient, not only for the cancer patient but for all patients. Now if one saw a patient who complained of pain in the abdomen and

vomiting once or twice the physician would frighten that patient by speaking of cancer with the result that the patient would suffer much more and would probably be sick for a much longer time. It was better to keep such a patient under observation and not to frighten him unnecessarily. A very careful examination by all the measures at our command should be made, and the rule should be that while we were doing everything we could to make a diagnosis we should never frighten the patient, but when we have enough proof to justify a suspicion of cancer we should arrange that something be done.

Dr. A. V. MOSCHCOWITZ said that both from past experience and from the two papers and subsequent discussion of the evening, he had gained the impression that patients with a carcinoma of the stomach were in a bad way. To some extent this was undoubtedly due to the fact that the medical profession was still divided into two camps, namely, internists and surgeons; and there was as yet an evident lack of harmonious cooperation between the two. Even so eminent an internist as Dr. McCrae spoke in his paper of his "surgical friends," and to Dr. Moschcowitz it appeared that the emphasis was strong enough to lead him to believe that "surgical enemies" were meant in reality. Dr. Moschcowitz was also of the opinion that first of all the idea of some internists, that to refer a case to a surgeon was a reflection upon his ability, should be abandoned, not only was it no disgrace to do so, but more than that, it should be looked upon as an agreeable duty.

Dr. WILLIAM H. STEWART said he wished to endorse the remarks of Dr. Hayes as to the value of the roentgen examination in the diagnosis of malignancy of the stomach. The most accurate findings made by means of the roentgen examination were in gastric cancer. These findings were persistent deformity in the outline as shown by the barium meal, which when combined with the clinical history of rapid onset with progressive loss of weight made the diagnosis almost certain. Cases showing deformity in the stomach outline that did not give the history of quick onset with loss of weight, were probably caused by contractions and scarring from ulceration. It was not always possible to differentiate between an old ulceration and an early malignancy, nor could we, from the examination, say that an ulcer was in the stage of beginning malignant degeneration. The safe rule was to consider all cases with persistent defects as malignant until proven otherwise.

Dr. MCCRAE, in closing the discussion, said that the point which Dr. Hayes brought out with reference to the choosing of an *x*-ray man was very good. The internist must be a good diagnostician of the *x*-ray man. In laying emphasis on the need of thorough examination it was not necessary to frighten the patient, but some patients were not willing to give the time unless the need for it was put strongly. In speaking of the relation of the internist and the surgeon he wished to place emphasis on the importance of sending the patient to the surgeon for an exploratory operation when that seemed to be indicated and not delaying too long.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, Held Wednesday, January 26, 1916.

THE PRESIDENT, Dr. JOHN D. McLEAN, IN THE CHAIR.

Diagnosis, Complications, and Treatment of Pneumonia in Children.—Dr. H. BROOKER MILLS in this paper said that various ages had been suggested before which the attack of pneumonia was apt to be in the form of bronchopneumonia and after which, lobar. Personally he felt that the age of five years was too low an age to be the dividing line. In diagnosing bronchopneumonia three important points for consideration were the age of the patient, history of previous illness, and the existing bronchitis. Three other symptoms nearly always present were increased pulse, respiration rate, and fever. Dilatation of the *algæ nasi* and definitely localized mucous rales also facilitated diagnosis. The physical signs, which were many and varied, developed early. The most common complication of bronchopneumonia, he said, was otitis media. The prognosis was always grave and the mortality was estimated by some at 50 per cent. The treatment was largely symptomatic with special attention to preservation of strength and upbuilding of vitality. A temperature of 65°, with plenty of fresh and frequently changed air

in the room, a maximum amount of liquid nourishing diet, daily colonic irrigation, daily bath, and plenty of water were indispensable in treatment. Counterirritation was valuable, and frequent and thorough cleansing of the nose and throat was absolutely necessary. For the cough inhalations were preferable to expectorant mixtures. For the high temperature Dr. Mills used hydrotherapy exclusively. In addition to the usual hydrotherapeutic measures he had found of advantage the wrapping of the hands and arms to the elbows, and the feet and legs to the knees, in wet cloths covered with a dry cloth, for twenty minutes three or four times a day. His patients were never disturbed after 7 P. M. for treatment, but in the event of their waking advantage was taken to meet the indications. The natural stimulation from nourishing, well digested food, was far superior to the artificial stimulation frequently employed too early in the disease. When, however, the heart needed assistance it should be given. Dr. Mills felt that he had been fortunate in having his hospital cases on a well lighted, protected porch adjoining the ward. He had made little use of the bacterin treatment because of the great variability of reported results and the uncertainty of dosage and reaction. Lobar pneumonia in children, he believed, was ushered in by high temperature oftener than any other disease of childhood, except scarlet fever. The onset was sudden with high temperature, rapid respiration, vomiting, prostration, and abdominal pain. For the first 24 hours, pulmonary symptoms and physical signs in the chest were absent; the chill, usually present in the adult, was rare in children, rigor seeming to take the place of the chill. There was practically no cough or expectoration in the first few days. Empyema was a frequent complication and there was no relation between the amount of fluid present and lung involved. In the present epidemic of pneumonia in Philadelphia many cases of lobar pneumonia had been observed in children below the age when expected, and these had occurred in debilitated children rather than in the robust child, as was usual. There had been also an increased tendency in bronchopneumonia toward coalescence of diseased areas, and the elevated temperature had been sustained rather than being of the usual irregular and moderate type. In several cases in the present epidemic an unusual fact was the enormous excursions of temperature between the hours of 7 P. M. and 7 A. M. He was at a loss to offer any satisfactory explanation of these various peculiarities; possibly the virulence of the epidemic itself might be a factor in their production.

The Diagnosis and Treatment of Pneumonia.—Dr. HOBART AMORY HARE said that consolidation of any part of the lung, whether due to the pneumococcus, the tubercle bacillus, or other cause, was in one sense pneumonia. Although from the etiological standpoint every case of pneumonia was identical, from the clinical aspect one case was often as different from another as smallpox was from chicken pox. In all cases of true lobar pneumonia it was to be remembered that the patient was suffering from an acute, infectious disease quite as specific as scarlet or typhoid fever. In the absence of a specific antitoxin one should not treat the disease, or the patient, with drugs except when definite assistance was demanded. In both bronchial and lobar pneumonia absence of positive physical signs as a group was often misleading in diagnosis. Fine râles and bronchial breathing were often apparently absent because of the great amount of exudate present. In such cases percussion might reveal dullness over a silent area; but even percussion might mislead because a deep-seated consolidation might give hyperresonance on light percussion over the area affected. The differentiation of effusion and pneumonia was easy in typical cases, and still easier in the textbooks, but often one of the most difficult problems in practice. Croupous pneumonia might assault a man frankly, or as insidiously as did a sapper his enemy in warfare. The sputum might vary greatly. In Dr. Hare's opinion it was well to recall the words of Sir William Jenner, "The brighter the blood, the less the weight of the patient, the better the prognosis." To this might be added, the higher the fever, the slower the pulse, the better the prognosis. In the treatment of croupous pneumonia Nature's laboratory should be allowed to make the needed drugs. Attempts to treat the pneumonia should be withheld. Cotton jackets and poultices, in the treatment of pneumonia, he regarded as remnants of barbarism. Coal tar antipyretics, he said, were contraindicated in all instances. There was a large amount of evidence that fever was a protective process or was

indissolubly connected with the protective processes. Except in cases of distinct hyperpyrexia with the temperature above 105° for a long period, even cold sponging was as a rule to be avoided, for the patient would not react. On the other hand, an agent which tended to lower temperature and permitted oxidation and which was as nearly a specific remedy as any in use, was cold, fresh air. When William Perry Northrup of New York instituted this treatment a great advance was made in dealing with pneumonia. Personally he would rather employ this method in treating croupous pneumonia than any drug with which he was familiar. It was hard on the nurses but life to the patient. A frequent mistake was that of treating symptoms simply because they were not in accord with the normal state. Any attempt to force the pulse, the respiration, or the temperature to the normal line was futile and dangerous. When, however, any symptom or series of symptoms became so widely separated from normal as to be dangerous or to indicate the approach of danger it should be fearlessly curbed. The administration of ten drops of tincture of belladonna three or four times in twenty-four hours throughout the great part of the attack of croupous pneumonia tended to prevent complications in the vascular apparatus. Atropine and strychnine were to be kept in reserve to be used in full dose to meet threatening collapse. Alcohol in the form of a good whiskey was often of great value in those of advanced years and in those who had been accustomed to its use. In certain cases, in which there was great cyanosis in plethoric individuals free venesection was sometimes of advantage. Estimation of the difference between the diastolic and systolic pressures was important. A diastolic pressure of 60 with a systolic pressure of 150 showed relaxed vascular tone, but a powerful heart stroke, and that cardiac stimulants were not needed; whereas, a diastolic pressure of 70 and a systolic pressure of 110 might indicate, in certain cases, that both vascular and cardiac stimulation was essential. With the possible exception of belladonna, used to prevent the sudden arising of complications, Dr. Hare had never seen any case of pneumonia which needed the same remedy in the same dose day after day. The skilled physician would fit the drug and the dose to the need of the patient at each visit. Expectorants in either type of pneumonia were never useful until the stage of resolution was developed.

Dr. JUDSON DALAND said one should be on the alert to diagnose bronchopneumonia in the absence of the ordinary physical signs, since the x-rays showed that the disease, particularly in very young children, was very frequently overlooked. He had oftentimes wondered whether in cases of bronchopneumonia with associated nasal obstructions exposure of the patients to the outer air, thus allowing direct entrance of the air through the mouth, was beneficial. He believed that the fatal result in many infectious diseases was often due to the lack of resistance rather than to the infection. With close study, the probable degree of resistance under certain circumstances might be estimated.

Dr. WILLIAM N. BRADLEY said that in his experience with bronchopneumonia in children the larger number had been of the primary type. In a series of 100 cases Holt found one-third to be of this type, a larger percentage than that given by Dr. Mills. Dr. Bradley said he agreed with Dr. Mills regarding treatment, expect possibly in his hydrotherapeutic measures. In his experience cold water was not well borne by quite young children. The initial chill of pneumonia he believed to be of more frequent occurrence in children than was generally thought. Whether or not the profession wanted to accept serum therapy this treatment, in his opinion, offered the ultimate solution of the problem of pneumonia. To be kept clearly in mind and taught was the fact that pneumonia was an infectious process.

Dr. WILLIAM EGBERT ROBERTSON said he was not a fatalist in believing that the pneumonia patient must die. He believed rather that the large number of deaths was due to the profession's ignorance of the disease and of the method of handling it. More frequently than was thought, he believed, pneumonia developed upon a substratum of a tuberculous process. It was his experience that pneumonia developed usually in individuals with a disease focus, if not tuberculous, probably intranasal or an old sinus disease. In some cases beginning apparently as pneumonia treatment of the nose would abort the disease, which fact supported the view that the nose might be a factor in the development of toxic forms of the organism. Whatever the

character of the pneumonia, the important element was recognition of the type in order that there might be evolved a successful treatment.

Dr. MILLS, in closing, agreed with Dr. Daland that there were probably many more cases of pneumonia than were diagnosed as such. He knew from experience that the x-ray was a very valuable aid in diagnosis in cases in which the clinical signs were either absent or atypical. Abdominal pain, he was aware, often led to the mistaken diagnosis of appendicitis. He referred to one case in which a prominent surgeon was called in to operate on the gall-bladder and in which autopsy revealed a bilateral involvement of the lung. It was fair to suppose that while the presence of tuberculous areas in some individuals might not have predisposed to pneumonia those areas provided a favorable culture medium for the pneumococcus and other germs in developing pneumonia. Personally he failed to see how it would be possible to abort a frank pneumonia by any form of nasal treatment.

Dr. H. A. HARE, in closing, said that while recognizing the possibility of the ultimate value of serum therapy in pneumonia he felt that there were reasons in opposition to this solution of the problem; for example, in a large number of cases when the physician was called there was already blood-tinged sputum, or exudate in the air vesicles. The process was in one sense complete. One might as well run for the cook stove, after water had frozen and burst the pipe, with the idea of melting the ice—the damage was done. Furthermore, in pneumonia the time of primary infection was not known. In typhoid fever when a man came for treatment he had been inoculated twelve to fourteen days, while in pneumonia the time was not known, although there were certain reasons for believing that inoculation had been within forty-eight hours. The presence of renal disease in a patient with pneumonia was of grave import in prognosis. Failure of treatment in such complication should not cast doubt upon remedies useful in the ordinary case. The same was true in heart conditions. Alcohol was of value in pneumonia patients since it dilated the peripheral capillaries, giving energy to the body and equalizing the circulation.

Report of the Pneumonia Commission.—Dr. DAVID RIESMAN, Chairman of the Pneumonia Commission, explained the appointment of the Commission as an outgrowth of a desire to find ways and means of lessening the incidence of, and the death rate from, pneumonia; and to study the cause, mode of spread, prevention, and treatment of the acute catarrhal affections prevailing in Philadelphia during the present winter. A similar work undertaken in New York City in 1904 had not, he said, been carried far enough to be of material value in lessening the death rate of pneumonia. Of all acute diseases prevalent in this climate pneumonia was the most serious and most fatal and the one responsible for the largest number of deaths. While the death rate from typhoid fever in Philadelphia had steadily fallen from 1,063 in 1906 to 111 in 1915, the pneumonia death rate had been practically unchanged and in some years materially increased. In 1914 there were reported in Philadelphia 1,436 cases of pneumonia; in 1915, 2,744. In December last 881 cases had been reported, the largest number in any one month. The number of cases reported, however, did not indicate the total number of cases, as, apart from the fact that many physicians did not report their cases, some of the complications of pneumonia were reported as the principal disease, the pneumonia, in reality responsible, being ignored. This was true of some cases of meningitis, empyema, and middle-ear disease. The present outbreak, it was said, had shown that pneumonia as an epidemic disease was as yet uncontrollable. While it had been held for years that the germ of pneumonia was present in the mouth of many healthy persons, it seemed that this was not the case; the germ actually found was quite harmless, while that causing pneumonia was virulent. This discovery had led to the conclusion that pneumonia did not always develop from within, but was conveyed to the patient in some way from a previous case. Another undertaking of the Commission was an investigation of the recent "grippe" epidemic. Circulars were to be sent out to industrial establishments, schools, police and fire departments, reformatories, etc., to determine the frequency of the disease and perhaps its mode of spread. Further light was also to be sought upon the mooted question, whether grippe predisposed to pneumonia. The Commission had divided itself into a committee on laboratory work and one upon clinical inves-

tigation, and the plans of the respective committees were completed. That which was needed for execution of the work was an adequate appropriation by the city. Such investigation was said to be of great importance to the city, but in the opinion of Director of Health Krusen it would assume an importance of national scope.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held February 28, 1916.

THE PRESIDENT, DR. FREDERIC E. SONDERN, IN THE CHAIR.

Report on Mills Bill.—Dr. SAMUEL J. KOPETZKY, chairman of the committee on legislation, presented this report. He stated that the committee on legislation had investigated the bill introduced into the Legislature at Albany which provided for the establishment of a system of insurance to provide benefits for employees in cases of death, sickness, and accident not covered by the workmen's compensation act. This measure gave medical service, nursing, drugs, appliances, and funeral expenses to all persons employed in the State at manual labor and earning less than \$100 per month. The committee considered this bill untimely because the workmen's compensation law was still in the experimental stage. Particularly was this true of questions affecting the medical profession. If doctors took work by a system of bidding the result would be poor medical service, and this would counteract any tendency toward reducing the amount of sickness in the State. Under this bill the State's interest became one of supervision and control solely, and for this the State was asked to pay one-fifth of the cost of maintenance. This was unjust to taxpayers. The only way to reduce sickness to a minimum was to introduce a system of State medicine and to ask the State to employ physicians and surgeons and to pay them a just wage, exactly as the State paid for other services rendered its citizens. The medical profession was not represented in the directory of health or trade associations, the insurance council, or the Insurance Commission. This was the basis for the opposition on the part of the committee on legislation.

The society voted in opposition to the bill in spite of a strong plea from Dr. S. S. Goldwater asking that action on the bill be deferred until the society's suggestions be submitted to Senator Mills.

Puerperal Gangrene of the Extremities.—Dr. ARTHUR STEIN read this paper, in which he said that the importance of puerperal gangrene as a menace to child-bearing women was plainly illustrated by the reports of seventy-five authentic cases in the literature, including four cases of gangrene after gynecological operations. The occurrence of two instructive cases in his own experience had led him to make a careful study of peripheral gangrene and of the literature on the subject. The first patient, a young woman of twenty years, with gangrene of the right leg following abortion, recovered after amputation below the knee. The second patient died of exhaustion with dry gangrene of both feet and lower legs after labor at term. The histological examination in the first case gave the diagnosis of venous thrombosis of the peroneal artery, necrosis of the skin, and superficial fascia, necrosis of the muscle, and periostitis of the fibula. This case was of interest because in looking over the records it was only the fourth case of gangrene setting in after abortion, which had been reported. The second case occurred after forceps delivery at term. In this case there was sloughing of the perineal sutures and dry gangrene of both feet and lower legs. There was no operation. The patient died, and no autopsy was performed. Since no autopsy could be obtained, it was only possible to guess at the real cause of this symmetrical gangrene, though the following explanation had suggested itself to the author: Thrombosis starting from the uterus extended into the uterine artery and from there into the internal iliac and common iliac artery up to the bifurcation of the aorta where it also occluded the other common iliac artery and by doing so caused the symmetrical gangrene. This was not the case with the first patient in whom the onset of the gangrene was rather slow and the gangrene itself of the moist variety. This immediately suggested an occlusion of the venous system in the affected leg with the arterial supply still working. It would be wrong to

assume that the obstruction of such a small vessel as the peroneal artery could be the only cause of the gangrene of the entire foot and lower leg, and it seemed that in this instance there was arteriovenous occlusion of the affected area, the venous obstruction being the primary affection. Dr. Stein, in reviewing some of the points suggested by the literature on puerperal gangrene, called attention to the investigations of Buerger, who studied the vascular lesions leading to presenile spontaneous gangrene and referred to thromboangitis obliterans as a specific disease which must not be confused with the conditions leading to puerperal gangrene of the extremities. He said there was no reason for assuming that the specific type of infectious organism which he considered responsible for thromboangitis obliterans was identical with the pathological agent of puerperal gangrene, a condition in all probability due to a mixed infection. In discussing the etiology of the condition, he said that Klein had found that there was one thrombosis in 500 births and one embolism in 9,000 births; Jaschke maintained that there was one thrombosis in 400 births and one embolism in 9,000 births. A very important cause of thrombi was the considerable loss of blood, whether due to parturition, operations, or other reasons. There might also be an abnormal constitution of the blood favoring the onset of thrombosis, described under the name of thrombophilia by Mendel. Puerperal peripheral gangrene of venous origin was very exceptional, the arterial origin being by far the most common and being probably always due to infection. Although the reason still escaped us as to why in certain cases the septic or toxic process became localized in the internal wall of an artery and in other cases in the venous wall, or in both, the most common cause of puerperal peripheral gangrene was known to be a septic or toxic endarteritis, and embolism from diseased heart valves usually occurred in cases of grave puerperal pyemia. According to the fundamental teachings on thrombosis, coagulation of the blood resulted even in the presence of sufficient circulation whenever the endothelium of the blood vessels was damaged in its nutrition and thereby in its physiological function. Besides septic infection, other causes, such as weakened heart action, probably played only the part of the last determining factors. Fraenkel stated that postoperative thromboembolism was directly traceable to septic infection having its entrance avenue at the operative wound, and the same was undoubtedly true for more distant puerperal thrombi which were likewise referable to a focus of infection. Arterial infection was either the result of a preliminary change of the vascular wall or of a change in the composition of the blood, or of a combination of both these factors. Changes in the blood itself usually affected the small and medium-sized arteries exclusively; whereas, very large vessels might be blocked in consequence of lesions of their walls through microbes or their toxins. The phenomena of incipient gangrene were identical with those of mechanical obstruction of the blood vessels and naturally varied according to the mode of origin and the path of the infection in a given case. Pain was very pronounced. Infection being usually the etiological factor, the ordinary symptoms of puerperal fever were apt to precede the signs of tissue necrosis. Septic puerperal endometritis was present in the majority of the cases. A sudden onset usually pointed to embolism in the arterial system (dry gangrene), while on the other hand the gangrene might develop very insidiously in the case of a small embolus which at first did not entirely block the circulation. In a general practical way it might be said that the early appearance of gangrene in the first few days of the puerperium pointed to an arterial origin. The prognosis of puerperal peripheral gangrene was governed in the first place by the timely performance of amputation, which was not always practical because of the bad general condition, the rapid progress of the gangrene, or because the seat of the obstruction was located high up in the aorta. Puerperal peripheral gangrene had accordingly a very bad prognosis as one-half to two-thirds of the patients died without its being possible at the present state of their knowledge to prevent or essentially improve such an unfavorable outcome. Nevertheless, the mortality had been lessened by one-half since the institution of modern methods of treatment. The treatment of beginning puerperal peripheral gangrene consisted purely of conservative measures, such as applied simply to the prevention of thrombosis and embolism by means of elevation of the extremity, cardiac stimulants, judicious transfusion, and similar measures. The appearance of the line of de-

marcation was the signal for surgical interference. The manifold instructive features of these cases were best brought out by a comparative study of the material in the general literature, and in order to offer this, Dr. Stein had prepared a number of tables showing at a glance which was the affected extremity and whether the gangrene was of arterial, venous, or other origin. The entire number of observations was 75, including 63 cases of peripheral gangrene following labor, with one personal observation, four cases after abortion with a personal observation, four cases occurring in the late course of pregnancy, and four cases after gynecological operations which had been added for reasons of completeness. The majority of the cases, 53 in number, concerned peripheral gangrene of the lower extremities. The left leg or foot alone was affected 16 times, the right leg or foot 15 times, both lower extremities 15 times. In 3 of the cases the affected side was not specified. In one case (Begg's) both hands, both feet, the tip of the nose, and portions of the ears were gangrenous. In Rouse's first case both legs, five fingers, and the right ear were affected. MacFarlane's case had gangrene of the right leg and right arm, and Lever's patient had gangrene of the left leg and left arm. Arterial obstruction through embolism or thrombosis due to endarteritic change was especially noted as the cause of gangrene in 28 cases. Disease of the heart, alone or in combination with arterial obstruction, was noted in 13 cases, and persistent foramen ovale in three cases. Obstruction of both arteries and veins was present in 12 cases. Venous obliteration alone was apparently responsible in nine cases. Although the cooperation of unfavorable circumstances which led to peripheral gangrene could hardly be foreseen and prevented, the safety of the puerperal patient would be decidedly enhanced if the possibility of such a formidable complication was kept in mind. A thorough knowledge of the predisposing causes and watchful care at the bedside were the only means to check a further swelling of the list of peripheral gangrene due to the puerperal state.

The Operative Treatment of Pyloric Obstruction in Infants, with Review of Seventy-seven Cases.—Dr. WILLIAM A. DOWNES made this report, in which he stated that 47 cases belonged to a recent series in which he had performed the Ramstedt operation. Thirty cases were in the earlier series, in which a gastroenterostomy was performed. The ages of the children varied from fifteen days to four months. With regard to the choice of the operation, it had been their experience that the Ramstedt operation allowed the stomach to empty itself in a more physiological manner, while the performance of a gastroenterostomy was likely to produce too rapid emptying of the stomach and caused intestinal disturbances. This had been observed in 50 per cent. of the cases in which the latter procedure was employed. There were certain cases which gave the classical symptoms of projectile vomiting, steady wasting, constipation, excessive stomach peristalsis, in addition to a palpable nodular tumor in the pyloric region, and these were the cases that must be regarded as cases of true pyloric stenosis. On the other hand, cases were reported without any palpable tumor but otherwise having all the usual symptoms in varying degrees of severity. The suggestion was offered that this group should be treated medically until they no longer responded, as evidenced by stationary or falling weight. These cases might be subjected to a laparotomy with its high degree of hazard. If a hitherto undiscovered tumor was found at operation, the infant might be able to stand a considerable degree of shock incident to the performance of a posterior gastrojejunostomy. If no tumor was found, little was gained and much was lost by subjecting an impoverished infant to the loss of blood and further depletion of its natural resistance. If, therefore, by the use of modern methods diagnostic means could be made so complete that one could with any degree of positiveness determine whether or not a given case should be operated upon, it would be an advance worth while. Whether the stomach in early infancy was simply a dilated pouch for the accumulation of food which was quickly acted upon by the gastric juice and immediately allowed to pass out through the pyloric opening, or whether it performed its share in the preparation of food for the more complex processes of digestion in the duodenum, was a question for future study. But Dr. Le Wald had shown by means of radiographs and the bismuth meal the degree of obstruction, and this had been of considerable help in indicating the advisability of operation. The question as to whether the pylorus would or would not admit a probe

or catheter at operation or necropsy was of little consequence when weighed against the clinical evidence of complete obstruction. There was usually sufficient time between the onset of symptoms and the appearance of the signs of complete obstruction for careful observation and the carrying out of any medical measures likely to prove of benefit. The fear, however, that the condition might have existed longer than had been suspected, and that the vitality of the baby was not so good as appearances would lead them to believe, made him feel that operation was indicated in every case of hypertrophic stenosis as soon as the diagnosis was made. Should depression or early evidence of shock be present, immediate operation was demanded. The babies coming to operation in good condition suffered little or no shock, their convalescence was straightforward, and they were at once restored to normal health. (See also MEDICAL RECORD, June 13, 1914, Vol. 85, page 1095.)

Therapeutic Hints.

Chronic Cough.—

R Terpine hydratis, ʒi.

Alcoholis, ʒi.

Syrupi pruni virginianæ, ʒiij.

M. Sig.: Teaspoonful three or four times a day.

Nervous Cough.—

R Codeinæ, gr. v.

Acidi hydrocyanici diluti, ʒi.

Elixiris aurantii, q.s. ad ʒiv.

M. Sig.: Teaspoonful four or five times a day.

Quinsy.—Cleanse the nose and mouth with a preparation of powdered borax, 68 grains; essence of peppermint, 20 minims; warm water, one pint, applied with absorbent cotton to the vestibule of the nose morning and evening. Apply daily resorcin, chemically pure, and distilled water, of each by weight, 2 drams, in the same manner to the affected parts. Care must be taken that no excess of this solution touches neighboring parts. Follow by guaiacol, 2 ounces; oil of peppermint and olive oil, of each one ounce. Apply either with cotton swab or camel's-hair brush to throat and inflamed gums twice daily. This last prescription stops pain. Suprarenal extract may be used instead of the guaiacol. The tincture of chloride of iron in glycerin and water, of each three ounces, should be given internally. If constipation exists, treatment with solution of citrate of magnesia should be carried out. When the abscess forms, open it promptly and treat with care to avoid adhesions.—Faulkner, "Tonsils and Adenoids."

Chronic Articular Rheumatism and Rheumatoid Arthritis.—Beverley Robinson considers that in the local treatment of these conditions nothing equals daily massage combined with active and passive movements. When this is not always obtainable and when local medication is desired, the compound tincture of iodine and the iodine ointment are more often preferable to the simple tincture of iodine. For internal use he prefers the glycerophosphates or hypophosphites of lime and soda, and Bland's pill mass in powder form. Cod-liver oil in combination with malt extract or the hypophosphites is an immense aid to nutrition. No amount of good butter or cream will supply its deficiency.—*Clinical Medicine.*

Ringworm of the Hands and Feet.—J. E. Lane begins the treatment of this condition by removing the superficial layers of the skin by soaking and then scrubbing with a moistened cake of pumice stone or sand soap. Sabouraud's treatment is next applied, if necessary, a 1 per cent. solution of iodine in 60 per cent. alcohol. If this be unsuccessful, a 1 per cent. chrysarobin ointment is used. The

treatment is discontinued for a while a week after an apparent cure has been obtained, and is then resumed for a few days in order to destroy any fungi that may have escaped.—*Boston Medical and Surgical Journal.*

Gargle for Fetid Breath.—

R Salol.

Salicylic acid, āā 0.2.

Saccharin, 0.5.

Vanilline, 0.1.

Alcohol (60 per cent.) 100.0.

M. Sig.: A small teaspoonful in a glass of hot water five or six times a day.—*Journal des Sciences Médicales de Bordeaux.*

Medical Treatment for Adenoids.—Falkner uses the resorcin treatment in all cases where operation is contraindicated. Chemically pure resorcin crystals and pure water, 100 per cent. of each by weight; another solution half that strength for infants. This is applied through the mouth, behind the palate, and up against the adenoid enlargement by means of a wad of absorbent cotton dipped in the solution and held in the grasp of properly curved forceps. The parts touched become immediately covered by a white coating. Applications are made once daily for ten or twelve treatments.—"Tonsils and Adenoids, Treatment and Cure."

Facial Neuralgia.—

R Menthol, 5.0.

Sulphuric ether,

Spirit of lavender, āā 50.0.

M. Sig.: Rub gently over affected area.

Ammonia as an Enema.—As a relief to the sequelæ of an abdominal operation, such as postoperative ileus and intestinal paresis, or in intestinal conditions in children, T. A. Black offers the following prescription, one dram of stronger solution of ammonia in one pint of water, administered as an enema; its effect is greatly enhanced by a hypodermic of pituitrin extract, 1 c.c. half an hour previously. The solution must not be used any stronger than prescribed, or too often, as injury to the rectal mucous membrane is liable to occur.—*The Lancet.*

Prophylaxis in Acute Abdominal Pain.—Robert P. Bay insists that acute abdominal pain be considered as serious until proved otherwise. Cathartics are contraindicated until there is an assurance that no inflammatory process exists. Small enemas are indicated, and peristalsis may be quieted by heat or ice; nothing should be given by mouth, and patient's head should be elevated. If immediate relief is necessary, Murphy's proctoclysis and a small dose of morphine (one-twelfth of a grain) may localize the pain. More good can be accomplished by lessening the peristalsis than harm by lessening the pain.—*Maryland Medical Journal.*

Brilliant-Green as an Antiseptic.—Archibald Leitch suggests brilliant-green solution in the strength of 1 to 1,000 for the treatment of all open wounds. Ordinary tap water may be used, but gives a precipitate, which can be avoided by the use of distilled water. Decinormal salt solution is perhaps the best. The wound is cleaned as in all surgical dressings and a small quantity of the brilliant-green solution, about an ounce, is applied with a syringe. The wound is lightly packed with gauze swabs dipped in the solution and covered to prevent spreading of the dye. Ordinary wounds are to be dressed once a day and septic wounds twice daily for the first two days, then once daily.—*British Medical Journal.*

NOTES ON AFFECTIVE PHYSIOLOGY.*

By GEORGE VAN NESS DEARBORN, M.D.

CAMBRIDGE, MASS.

(From the Sargent Normal School for Physical Education, Cambridge, and the Forsyth Dental Infirmary for Children, Boston.)

* * * *

I VENTURE to suggest the probability that *the physical or energy-aspect of feeling is numerous sets of kinesthetic neurokinetic strains or impulses relating all layers of the great cortex to its effective environment (whether the latter be outside the body or within it), the conscious inhibitory phase of the kinesthesia representing originally the feelings unpleasant in tone, and its subconscious actuating phase the pleasant emotion.*

It is to be explicitly understood that "kinesthetic" is here used in its wide sense to include among other things whatever afferent guiding information comes up the cord from the vegetative organs (from smooth muscle and possibly from the glands); and it is certainly superfluous to remind you that most recent modern discussions of emotion accept its motor "basis,"—in short, the James-Lange theory of the emotions,—this therefore will be pre-supposed. My sanction for my thesis is that careful consideration reveals coincidences and correspondences which make it worthy at least of annotation. It is an argument for mechanism no more than for animism. It tends to their arbitration!

Every research report and clinical study known to the writer tends to the certitude of the supposition that the great cortex contains, among many other things related to this very complex nature of ours, numerous functional sets of neurones which serve *symbolically* to represent in condensed form the widespread afferent influences from the abdomen and thorax and from the other elements (such as the blood-vessels (?) possibly) of the vegetative mechanism. In an homologous way, the cortex represents symbolically the influences (circuits) made from reflex groups of cross-striated muscles in the spinal grey-matter, these, the proper kinesthetic influences, being of two phases, actuating and inhibitory. These lower integrations up and down the spino-autonomic nerve-masses represent the kinesthetic "skeleton," as Ribot terms it, of every conscious state; they are subconscious but are always sublimating into consciousness more or less, but symbolically, through the cortical integrations and associations above in the cortex.

III. *Actuation.*—These neurokinetic strains or

*Read, q. s., before the American Psychological Association at Philadelphia, December 29, 1914.

*Because of lack of space it has been necessary to condense this article as it appears here, the omissions being indicated by the stars; the complete article will be published in the author's reprints.

influences (nervous impulses) pushing ever upward from the autonomic and the spinal grey into the brain are kinesthetic *resultants* of numberless forces coming from the entire body and ultimately from the environment. They represent psychologically, it is plain enough, the impulsive aspect of behavior, the impulse to activity, the biological egotism, animal aggressiveness, vegetative initiative, or whatever other term may be applied to it that is descriptive as well as denotative. They represent, in short, *actuation*, and most often they certainly stand for whatever is of pleasant tone to the affective aspect of the mind experiencing them so long as that mind is naïve and unsophisticated.

The "numberless forces coming from the entire body and ultimately from the environment" which fuse and interact somehow to produce these actuating resultants, it is not time yet to be able to describe in detail, although facts accumulate even here. For example, two general classes of energies are to be discriminated. There is, first, a group of afferent strains which represent the movement or *motion* to which we now reduce all protoplasm as we do all other matter. Living matter seems to be "alive" and not dead chiefly because its molecular and electronic movements, and therefore its molar movements, are greatly more complex than those of matter we conceive as non-living. I have already in sundry places set forth this matter, even if feebly.^{17, 18, 21} In my humble opinion much practical benefit would soon grow out of a general awareness of this basal truth,—that the inherent nature of protoplasm itself as matter furnishes inevitably the impulse to activity which underlies all feeling and emotion, or if you prefer it so, is concomitant thereto. It is this first group of afferent strains of course over which the autonomic system rules, doubtless with multitudes of more properly kinesthetic impressions from the voluntary mechanism fusing with them in the cord.

The second large group of ingoing actuating impulses more literally represent the environment of the total individual and to a degree transmit its energy kinetic, thermic, photic, chemic, magnetic, or whatnot, but always transformed, into the spinal grey. These impulses pass inward to the posterior and lateral white and grey tracts, fuse infinitely, join the foregoing group from the more strictly vegetative parts of the organism, and altogether help largely in determining the resultants which pass upward to the cortex cerebri, as will be somewhat more fully detailed by and by.

* * * *

Obviously the motivations of the feelings spring out of these kinesthetic strains or tendencies to action representing either symbolically or directly (as above discriminated) the animal's biological reactions to its ever-changing environment, without or within. The innervations arising thence—that is,

the behavior—would be actuations and not often inhibitions, and would represent to the world without, as well as to the personality within, the “unimpeded” and “undeflected” satisfactions of some kind, some “original tendency” to biologic furtherance,—in short, that universal tendency of biologic egotism by whatever other famous phrase we may denote it. As I have tried to show elsewhere,^{18, 21} the impulse to activity has in it and in close relation to it almost a tainted wealth of theoretic and practical applications in psychophysiology and in educational practice. At this time we shall leave it, only summarizing our findings up to date, one side of our shield of proposition, that *in the naïve and wholly normal individual the inherent impulse to movement in space and in time is represented neurally by the actuating phase of kinesthesia pleasant in tone whenever it rises out of the subconscious.*

* * * *

IV. *Inhibition.*—It is, however, the other (inhibitory) phase of this reciprocating process of general affective innervation to which I would more especially call attention, for it has been far less specified than the actuating other just suggested. Too little emphasis certainly has been laid upon the twofold nature of human personality, upon the complete *duality* of man's nature, especially to its physiologic and psychologic foundations. Poets and philosophers have seen and beautified its moral aspects, and have shown in terms that cannot be forgotten that the sanction of our very conception and incarnation and birth and living lies all but wholly in the logical necessity of developing individual personalities through temptation, struggle, “denial of the will-to-life.” Whether we see it every day in the unselfish self-denial of the dear women in our own households or read in leisure hours of its esoteric system in the wilds of ancient Thibet, we are continually made aware that it is one of the dominants of our actual world.

And when we turn to the anthropologic aspects of this same matter we find our fundamental just the same and find it closer to physiology and neurology. The phylenic “series” shows at first a preponderance of biologic egotism, of racial impulse, of pleasant activity, expansion, push. There is excess of movement over control, the utter mechanism of the plant, the tactic processes of the protozoa, the simple behavior of the early metazoa, play, the noise and irresponsibility of childhood, the dance, boisterousness, freedom of every kind, the grand flourish, license, extension of personal and family and national power, “might makes right,” “to the victor belong the spoils,” force, great guns, invasion, pleasant hopes of conquest, freedom to progress even in the sun regardless of all but one's self.

But the secret of the sanction of our incarnation lies not here! Rather does it lie in a process which uses all this as Emerson says, “as hands and feet” by which it may accomplish its great world-purpose each in his own individual way. I mention such relations in this discussion of physiology (which ordinarily tells none too much of God and personality), only to show how important and basal and deep and universal are the ramifications of world-processes which at heart are in practice muscular and nervous and even epithelial. And it is worth while to see it so.

Man, then, generically and individually becomes civilized, even if slowly, grows up, attains the full measure of a being who “dares do all that doth become a man,” even to attempted conquest over the

vegetative and biologic machinery which gives him his *energy*. He restrains his impulsive machinery, serves as governor to his flywheel, so to say, often so massive and with such dreadful inertia of motion! He learns to inhibit especially his emotions and thereby, more than in any other way, qualifies for a citizen of our little world against whom that world will not rise in wrath. It is of course now our hunt to trace out some few details at least, or relative details, of the nerve-paths and nerve-knots of that inhibition, especially in relation to the algodonic tone of the emotions and the feelings.

It has already become reasonably certain that freedom in itself is pleasant, and that restraint biologically speaking—that is, naturally, in naïve individuals—is inherently disagreeable, whether from without or from within. I would emphasize the provisional clause in this part of my thesis, “biologically speaking—that is, naturally, in the naïve individual,” for we shall suggest below that it loses this unpleasantness as the person becomes a psychologic personality. As the wise “George Eliot” says in “Felix Holt,” “There is a sort of subjection which is the peculiar heritage of largeness and of love; and strength is often only another name for willing bondage to irremediable woes.” We all know that freedom as such is pleasant, and a seven-foot shelf of books, or one even longer, might be readily written, given time, to extol freedom's pleasures in every possible realm of human experience. It has, I think, not been often effectively suggested, on the other hand, that in the unsophisticated animal, dog, or child, or savage, inhibition is essentially and inherently unpleasant (until, by submersion—see below—its disagreeableness has been mostly lost).

In the *Journal für Psychologie und Neurologie* for January, 1913, experiments by the present writer were reported which suggested, if they did not prove indeed, that the conscious phase of our movement-sensations or kinesthesia has a distinctly inhibitory influence over cross-striated muscular action. A paragraph or two from this report may be quoted:

A. Of the results of this research, perhaps the most interesting for the physiology of kinesthesia is the fact that reinforcement of the conscious movement-sensations by deliberate attention to them tends to shorten the movements and to somewhat lessen the angles between them. In other words, in visualizers, intensification of the conscious kinesthesia inhibits the related voluntary movements. It is difficult to avoid the conclusion, such being the case, that *the function of the conscious movement-sensations is the inhibition, the deliberate active restraint, of tendencies to action.* Attention to matters other than the resident kinesthesia of the active arm, as was demonstrated by trial, tends to stop the performance altogether or to make it irregular, uncertain, and wabby. Attention to the resident kinesthesia, on the other hand, tends simply to make the movements less, while they continue deliberately to the end without hesitation,—but minimized. Considering that the movements studied are free-arm movements from the shoulder-joint, tending therefore to exaggeration far beyond their true size, this result becomes all the more striking. Almost no records, per contra, showed enlargement under these circumstances, also a significant fact where the voluntary conditions are so complicated and uncertain. Fifty-five per cent. of the reactions showed this inhibitory effect and just about half of the subjects made reactions consistently that

were of this type. May we not conclude that the more or less conscious resident kinesthesia, perhaps distinct from other kinesthetic coordinations, has special inhibitory function, as well as the passive reception of jars, vibrations, passive movements, and postures?

B. The fact of the prompt and usually accurate *visualization* of the movement-series received into the person's central nervous system solely through the kinesthetic receptors of the arm, is an interesting product of this experimental work. Often the subject reported a clear visual image of the norm after receiving it (kinesthetically) only once, and often he proved its existence and its accuracy by drawing it (on the basis of a visual motor idea). The paths of these kinesthetic impulses and their production of a visual image constitute a problem of especial interest for the physiology of efficiency; and they would explain the conception of space in the blind. This process of visualizing varied much in different subjects. It was best and promptest in visualizers long trained in delicate motor adjustments. It was least conspicuous in the three subjects (two young women with normal vision and a youth congenitally blind) whom the psychologists would class as motiles. (See below.)

In any case, this prompt and usually involuntary, translation of a complex and purely kinesthetic impression into a visual image is sufficiently striking in itself, however familiar a process, and leads inevitably to a query, as yet unanswered, Why? Why cannot and does not the man of average motor skill use his conscious kinesthetic impulses in the guidance of a movement, especially a movement about which is known nothing else? Perhaps one reason that he does not do this lies in the inherent inhibitory action of the conscious kinesthesia—and the other phase of kinesthesia his imagination knows nothing of. But aside from this in part, the *opposition* between the resident sensations of movement (inhibitory and more or less conscious) and the "visual" and other actuating influences, is marked, and the fact may prove suggestive. Even when reinforced by conscious effort, the resident kinesthesia and its centers (in the great cortex?) had usually no conscious memory of the norm as a whole, had nothing in fact usable as a motor idea, and the subject (unless a motile) thought himself wholly dependent for an efficient performance on a second-hand, mediate, visual image, product of the immediate impressions none the less which he supposed himself unable to follow as a guide. * * * The conclusion is inevitable from these circumstances that there must be kinesthetic nerve-impressions in closest relation with the visual neurograms proper, yet obviously unconscious, that do furnish the data necessary for a voluntary movement, and that actually do coordinate the muscles active in an action. This phase of kinesthesia, actuating, determinant of the force and speed of a movement perhaps, but sub-conscious or even unconscious, represents, it seems, the innate impulse to activity, the instincts, the emotional syndromes, the reflexes—the correlation of all the forces behind a voluntary action. This phase of the movement—"sensations," however, do not represent the individual personality of a human being until complemented and held in leash, inhibited, by the conscious resident sensations. We cannot escape terming these actuations, coordinated perhaps in the posterior grey cord, kinesthetic, for their nature and use are inconceivable apart from the joints, muscles, tendons, bones, and skin, the chief

locations of the kinesthetic receptors. The opposition between these two phases of motor control, actuating and inhibitory (the former including vision and audition), is eminently natural for most people, then; but it is an opposition that is in reality an alliance and capable always (skill) of fusion for efficiency.

The inhibitory factor in the glandular and muscular activities of the vegetative mechanism is already to some extent commonly appreciated, there being in this all-important domain of the total economy an elaborate apparatus, partly kolonic and partly autonomic, for the active restraint of vegetative activities or tendencies thereto. Barker has concisely set this matter forth,² and perhaps better than another; it has already become the basis of important developments in therapeutics. (See below.) For us at present these inhibitory functions have especial interest in the theory of feeling and emotion as explained by Lange, while James' part of the "theory" involves more directly the afferent neurokinesis commonly thought of as kinesthesia proper, and concerned directly in the simple research referred to above.

It seems to suffice for our present concern in affective physiology to point out that the inhibition of impulsive tendencies (mostly pleasant on well-accepted principles) is by their very nature usually an unpleasant process. Even if unaware of the fact from personal experience, the reader cannot fail to realize that sometimes the restraint of our impulses, of our biologic, vegetative instincts in particular of course, rises into the heroic, involving as it does a maximum of struggle against unpleasant lacks of action along ancient hereditary paths. To restrain one's fatigue, one's wrath, one's hunger, or one's lust is oftentimes, to many men and women, their experienced maximum of disagreeableness. These are gross examples which the check to the onrush of biologic satisfactions, teleologic intentions, sufficiently "explains" to the average student of neurological psychology. It should, however, be noted as we pass them that in this contest between an impulsive process and a tendency to its restraint obtains the precise relationship to which early psychological biologists (*e.g.* Romanes) ascribed the origin of consciousness in the evolving phyletic order. McCabe's notion³ is far less satisfying: he actually refuses to admit the consciousness of animals less complex than birds, a truly Cartesian sophistry; but "the worse is not the better reason," after all.

For our present purpose it is an important consideration that in the personal, as well as in the social consciousness and memory, unpleasant experiences actually are more conscious, more vividly real, and much more memorable than pleasant experiences. And this is true as a well-realized fact wholly independent of any theory of feeling or of neurology. It is the blizzards, not the periods of delightful weather, which are remembered; a moment or an hour of agony agitates the memory long after ecstasies have gone, almost past recall. This is not due to some inherent pessimism in the human mind, we may be sure, for the majority of folk are practical optimists. It in part is due, say I, to the basal physiologic condition of innervation, namely that the conscious kinesthesia underlying mentally the movements concerned is more closely related to unpleasantness than is the actuating movement-neurility.

Another reason doubtless arises in the fact that the grand mean balance of human experience is

pleasant rather than unpleasant; on this basis alone would a human people with power of initiative to suicide remain in the long run alive, for "Lo, you are free to end it when you will!" Here, then, is a background of moderate pleasantness and against this the lurid experience of pain or of the disagreeable in any mode stands out with far more distinctness than would an experience toned like the background. As we pass, it is worth noting that almost all the behavior of the average adult is physiologically impulsive and reflex and semi-automatic, what we may best denote perhaps as habitual voluntary action. As thus impulsive it is pleasant because relatively free. As thus voluntary and inhibitory only to a slight extent, strictly voluntary²⁰ only at extremely rare intervals and in many persons never, after childhood, it has little of the difficult unpleasantness which is related to the kinesthetic foundations of restraint. To the galley slave, "Jean Valjean," life for just the opposite reason was unpleasant and revengeful, inhibitory, fearfully voluntary, a memory to embitter eternity. We return then to our scenario with widespread evidence that free action is by nature pleasant and inhibition, characteristic of voluntary movement, whether devised from within or forced from without, difficult, unpleasant, and hard.

There is a ground more precise and somatic even than this for proving conclusively that by its inherent nature restraint is hard and therefore (at first! and physiologically) disagreeable in so far as a voluntary, that is, new, process. Undoubtedly there is a far more elaborate system of reflex inhibitions^{16, 19} than has been as yet described in detail, and many of these automatic restraints may be importantly involved in the innervations of feeling, but these are too little known at present to be discussed at any descriptive length. We must urge, however, on the principle of the usual physiology of organism in general, that these afferent inhibitory paths are probably numerous and important, especially, it may well be, in early life. We are as yet only at the threshold of our knowledge of inhibition as a whole half of animal life; and its relationship especially to the ever-rising *individuality* in disparate units of protoplasm (as opposed to its vegetable aspects) is a field of philosophic biology scarcely touched, yet a wide and fertile field. From common physiologic principles, I repeat, on grounds most general and well known, it is probable that there is an elaborate system of restraint-paths which form part, the first part, of the neural circuits²⁰ having to do with bodily coordination. The last five years of physiology have emphasized the kolonic (chemic) portion of these inhibitory influences but always in relation, so it seems, to neurility one way or another. "It must be," it is likely that there are, numerous inward inhibitory pathways which control the actual empirical movements of the body, regardless of the histologic variety of contractile tissue producing them. The certain experiments already referred to¹⁴ show from the human actual psychologic side that they do exist.

We are especially concerned now, therefore, with inhibitions that are voluntary until by habituation they have become more or less mechanical. As example of one of these basal voluntary inhibitions closely related to the emotional tone-balance consider the checking of muscular movements when listening to real music. By real music is meant music with a wellmarked rhythmic beat. If one at-

tend many orchestral concerts, even where the music performed is of the very "highest class" and the audience the most "cultured" group of society, it cannot fail to be noted that the spontaneous, that is real, enjoyment is greatest from the music with strongly marked rhythm, and least, with a forced fashionable applause if any, at the artificial concoctions which ramble instead of march. At a recent concert, for example Beethoven's symphony in F major (Eighth) was in contrast, after an intermission, with Stravinsky's impressionistic and unrhythmic "Feuerwerk," vastly to the hurt of the latter, bad as it is. Some of the modern music forgets or ignores this neuromuscular basis of musical emotion and offers concatenations of harmony when the truly appreciative listener craves only what his inevitable organism demands to satisfy it—sympathetic and synchronous activity. Thus music or that which pretends to be music now and then strives to express ideas when its sole language properly is feeling or feeling with a tinge of will.

True music then, we are sure, has a well defined rhythmic beat and is met in the naïve and natural individual at whatever age by voluntary muscular movements of the feet, head, or hands; within oftentimes are corresponding but ill-defined contractions of the vegetative organism. Now to inhibit these (unfashionable because disturbing) movements is distinctly an unpleasant effort and takes away from the musical enjoyment and continues to do so in a measureable degree at least long after the inhibition-habit has been thoroughly acquired. One longs subconsciously, so to say, that he might hear such music when he were free to meet it in the natural way. Here, of course, is the basal psychology of the dance, and likewise to watch dancing while standing or sitting still is an unpleasant experience and that despite the joy from the well-marked music. In all this, it seems plain, we have the somatic (neuromuscular) prototype of the pleasant unimpeded impulse and of the unpleasant experience of inhibiting this impulse both being essentially kinesthetic.

This vegetative impulse furnishes the ways and means, the thrust and push, the substantial and inherently enjoyable activity even to abandonment which makes life interesting. On the other hand, the restraint of all this to suit the needs of a social environment, requires strife and weariness whose only reward is itself. There is here, however, the half of the personality, in fact that part of the total human behavior which is commonly deemed (but wrongly, we may see) the very essence of humanity, of civilization, culture, delicacy, or whatever other term marks off for us our proud humanness from brutishness.

As homologous hemi-thesis, then, let us say that *in the naïve and wholly normal individual the human restraint of impulsive movement in emotion is represented neurally by the unpleasantly conscious inhibitory phase of kinesthesia*. Sometimes this dysphoria has sunk out of consciousness as an explicit disagreeableness and we are in doubt whether the feeling be a pleasant or an unpleasant syndrome, but ordinarily there is obvious relationship between the degree of bodily inhibition and the dysphoria of the condition. Terror, for example, largely loses its painfulness when we combat or when we flee, and joy which is bodily restrained lacks its essential delight, in the naïve and normal, at least.

In the broad and modern sense of the term kinesthesia, these nerve-impulses and their like concerned in integrating the infinite bodily movements and inhibitions of which these are but examples, are kinesthetic, for they are afferent influences concerned with movement. But, regardless of terms, these and similar facts show in a new way, later than Sherrington's important "reciprocal innervation of functional muscular antagonists" (famous in form as in matter, but not so hard as it sounds), that pervading every aspect of the nervous system's work is this fundamental opposition of actuation and inhibition.

Nothing can be more important to a real understanding of the nature of human personality and human behavior as human than this duality, and I recur to it for the sake of emphasis. The human being is human essentially in direct ratio to his own habitual active inhibition. Obviously some are too human, too cultural, too civilized so as to suggest art and artificiality, prudery, prigery, snobishness, etc. This danger of excess, however (universal in all things good or bad) in no wise militates against the truth of the basal proposition that *organic evolution is at heart an ever complexifying process of control*. And control comes hard and because it comes hardly it comes slowly.

Beneath all this gradual age-long suppression of the impulsive beast is man's affective nature, for his emotions and feelings forever furnish the most part of his motive force, and we may see in his emotions and even in the physiologic conscious kinesthesia in part beneath, in turn, these emotions, the necessary physiologic and anatomic basis of this whole important life-duality. In directer phrase, the whole body is integrated and given meaning by an inhibitory mechanism as yet by no means understood in detail and the action of this restraining phase represents fundamentally novelty, therefore difficulty and therefore in turn unpleasantness. Just as in voluntary action²⁰ truly voluntary movements are new and difficult, so in emotion and in feeling, but less obviously. Every affective restraint or inhibition represents an unpleasant checking of a pleasant impulse, a narrowing of the biologic egotism, a more or less difficult adaptation to an environmental attitude, which adaptation is relatively new. The conscious and inhibitory phase of kinesthesia typifies this conscious disagreeableness in emotion as in truly voluntary action.

But lest I be accused of stating something not appreciably true in the immediate experience of my readers ("my conscious kinesthetic impressions do not feel, that is are not at this moment, unpleasant"), I am compelled once more to point out that none of my readers are any longer naïve in the psychologic sense, and that they cannot therefore judge by immediate experience whether in the child the inhibitory kinesthesia is unpleasant or not; that so far as voluntary movements are concerned they seldom make one that is physiologically in strictness voluntary, that is, new; and that so far as emotional inhibitions are concerned, in many cases the original disagreeableness of restraint has lost much of its sting by familiarity and habituation, while, on the other hand, certain kinds of emotional inhibition obviously may be unpleasant far beyond the unpleasantness of pain itself.

On the contrary there are two things (they appear to be but examples of many) which suggest that, to the young child, restraint, inhibition, personal control, whether in voluntary movement or

in the feelings, is eminently unpleasant: First, the extreme infrequency of such acts of will, in itself prima facie evidence that they are disagreeable experiences, since agreeable acts tend to be learned early and to be frequently repeated. Second, direct observation (see, for example, "Moto-Sensory Development,"¹⁹ p. 89, Day 211) shows a long latent period (ten seconds or so) for such difficult voluntary movements, resolved at length by a quick and frequently clonic motion, the whole suggesting difficulty physiologic and hesitation and unpleasantness psychologic.

Barrett of the lamented Louvain University, in his too little known "Motive Force and Motivation Tracks,"²¹ careful and extended research along novel lines, speaks as follows regarding the hesitation to drink a disagreeable liquid, a summary of the subjective experiences of many: "The fact that some hesitations cause a great lengthening of the reaction time while others do not affect it, suggested to us that there might be, so to speak, a purely psychical species of hesitation, and also a semi-physiological species. This supposition was strengthened by the fact that in some very quick reactions, wherein were painful hesitations, the subjects spoke of mental suspense and 'purely mental hesitation.' On the other hand, the semi-physiologic hesitations seemed to be accompanied by feelings of fatigue, disgust, and physical oscillations of the hand or the eye." Again, on page 175. "In general, then, hesitations occur much more frequently in disagreeable choices, and seem in a certain sense to be conditioned by them, just as they, in a certain sense seem to condition inconsistencies. Indeed the unpleasant experience of choosing between two disagreeable substances tended to inhibit volitional functioning, and, to justify the theory formulated by Mr. Stout: 'In principle it seems a safe generalization that agreeable experience is favorable, and disagreeable experience is unfavorable to the effective discharge of mental functions.'" Stout's belated opinion here is of course that common to most psychologists who have thought about the bodily concomitants of feeling, but, so far as the present writer knows, it has not been commonly recognized that perhaps through experimental studies like that of Barrett we shall find the easiest road to knowledge of the psychology of inhibition and of abulia; nor that an elementary principle underlying the will's action certainly underlies also the innervation of feeling, since "will" and "feeling" are but quality-aspects of a process completely common to them both.

I believe that Harvey's recent exposition²² of the origin of feeling has in it much material for thought by those who are satisfied with the wondrous magical powers of the "synapse," and certainly just now there are many who are more or less content to let this word synapse represent a whole science. Feeling, says Harvey, is perhaps "the concomitant of the resistance which a nervous impulse encounters in passing through a nervous arc." This obviously is a particularization of Romanes' explanation of consciousness, and represents a basal fact, but the author somewhat exceeds the sanction of common experience when he says (p. 94) that "in general the [algodonic] tone of the feeling depends upon its intensity. This is a matter of direct observation, and corroborates our theory of the resistance being the concomitant of feeling. A few possible exceptions to the general law will be noticed later." Moderate feelings, weak

emotions, are however certainly not all pleasant (worry is a notable example), nor are all strong feelings disagreeable, as such a dictum requires. But, on the other hand, there certainly is a correlation between the novel inhibitory or hesitations difficulty of an innervation and its unpleasantness. The ancient wisdom that one in time becomes accustomed to anything is but common recognition that emotions tend to lose their original unpleasantness by use, by habituation on the universal principle, whereas novel environmental situations producing strong emotional reaction have with them usually an admixture of unpleasantness. This, physiologically, I take it, is a restraint, a hesitation toward the unfamiliar, an example of the inherent unpleasantness of uncertainty.

V. *Integration*.—Possibly the above considerations are already enough to suggest to an unprejudiced mind that there is some kind of a direct relationship between doubt, hesitation, restraint, and inhibition proper and the unpleasantness of feelings. This concomitance seems based in the dual structure of the nervous system itself, and it is perfectly possible but not yet to be actually proved in a corresponding duality in the mechanism of muscle, both voluntary and vegetative. Discoveries in physiology continually are making clearer and clearer that this duality of action, this eternal balance of actuation proper and of active restraint, is the fundamental law, if there be one, of the animal economy; and that it is complex and complete in ratio to any animal's generic (and perhaps personal) status of evolution. Plants, on the other hand, it is worth noting for the sake of logical completeness, wholly lack any semblance of the inhibitory phase—a dim actuation-contentment would be their consciousness if they might be said to have any at all, a growth of satisfied beauty, "its own excuse for being." Personality, on the other side, and particularly the only personality of which we as humans can be sure, namely human personality, has its essence in an habituating system of restraints, at first unpleasant, but which gradually lose their consciously unpleasant tone, while retaining for the most part their inhibitory physiologic nature.

That these inhibitory innervations, representing unpleasant restraints of pleasant impulsive tendencies, are directly based in the conscious inhibitory phase of the kinesthesia broadly taken, is a probability too obvious to require elaboration. Unless the experimental observations referred to above¹⁴ are false the conscious kinesthesia is inhibitory in its influence on voluntary movements, and no one probably has reasons to suggest why it should not be on emotional reactions also, while we are fully certain that the vegetative reactions have well-defined inhibitory influences. It remains, then, to integrate a few of the recent advances in physiology and in the relations of mind and body; we shall then see that the central mechanism involved meets every conspicuous requirement of our hypothesis as to the innervation of the feelings in the great cortex, especially by the two layers of the cortex, which are respectively the first and the last to develop and to be completed.

If we may venture to make arbitrarily concise our present notion of the primary innervations concomitant to feeling and emotion, we may divide them into two classes: One set of innervations is chemoautonomic in origin and represents the chemical (hormonic) control of the smooth muscle of the body (present *everywhere* save in the bones, the

nervous system, the gland-acini, some sense organs, the connective tissues, and the voluntary musculature) through the intimate relationship between the autonomic neurility and the hormones at the myoneural junctions, and by no means wholly motor or efferent. The other set of primary innervations flooding the spinal grey is purely kinetic in origin and represents the movement universal in the parts actuated by voluntary muscle, half the body's mass. This is the kinesthesia in the narrow sense, and seems to be in two reciprocal phases, actuating and inhibitory, perhaps corresponding in this duality with the nerves now known to control the muscular synergy.

These two sets of autonomic and spinal circuits act on and in the spinal grey and somehow (just how is a mystery profound at present) prepare for the use of the integrating mechanism above in the brain, the great organ of wide adaptation and control; summaries or epitomes or synopses or *symbols* of some sort or of some other denotation which the present writer has commonly called *resultants*, a term borrowed from mechanics and the correlation of forces. These resultants, representing adaptive bodily movements and never separate muscles or muscle synergies even, it appears, pass upward by paths repeatedly considered into the optic thalamus, in part directly through the brain stem and in part by way of the equilibrating and integrating cerebellum. The thalamus distributes what it receives, how much or how little altered we as yet do not know, to the entire cortex cerebri.

If reference to another previous article¹⁵ be not taboo, it may be stated that in 1907 an article in the *Journal of Nervous and Mental Diseases* set forth at considerable expense of the two commonest kinds of ink that the muscles and all the other active forms of body protoplasm represented through their inherent protoplasmic motion the mental aspect of the animal, the Rolandic area and the remainder of the cortex, save as coordinators, being inadequate rationally to achieve that great end. I have in no important sense modified that opinion, but recent little discoveries and devices of understanding have tended distinctly to emphasize the principle of resultants, which flow upward from both the autonomic and the spinal greys. Thus it has become clear that the cortex and its preliminary ganglia as way stations are by no means dependent from moment to moment on the stream of afferent influences coming singly directly from the moving somatic units in the relative environment. By one of the functions peculiar to a nervous system, as yet wholly unexplained, a group of neurones, large or small, has the power of subsuming by a process of symbolism the control of functional regions and mechanisms not immediately in intimate connection with it. Facts of neurology, of pathology, and of surgery too numerous to be mentioned positively demonstrate the activity, the great degree, and the relative perfection of this wonderful power of vicarious control, of subsumption we may call it, in the nerve centers. The phenomena of ambidexterity, the useful if trite "American crowbar case," the surprising facts developed by the surgery of the cranial nerves for the relief of intolerable neuralgia, are instances familiar to all.

Applied to normal development and neurologic symbolism or subsumption, these facts are far more easily understood, for, as Ramon y Cajal and others have shown, neuronal growth, the actual development of dendrites, collaterals, teleodendrites, and

"synapses" proceeds directly under the influence of stimuli coming in functionally from already developed and acting parts. Thus it is, somehow, that a little knot of neurones, whose cells at least are in the spinal grey, can stand for, integrate, coordinate, symbolize a greatly complex apparatus of nerves and muscles in many far-separated parts of the body; and thus it is that one of the prevertebral ganglia of the autonomic, for example, subsumes the control of a whole functional system of glandular activities, such, for instance, as the actuation of the indispensable adrenals. Thus it is, too, by a process more elaborate but wholly similar it is likely, that a knot of neurones in the brain subsumes and integrates a complex set of processes each in itself complex and intricate.

But still more than this and much more germane to our present purpose: these higher centers seemingly become after a time, when adequately developed, independent of their proper immediate influences from below and able to associate with each other in their turn for their ultimate purpose of representing in a sense and realizing the stream of mind. This last complexity, indeed these two last complexities, are, at length, true symbolisms, for nothing immediate from smooth muscles and glands and cross-striated muscles, synovial membranes, bones, tendons, etc., nothing at all in short from the universally moving tissue-protoplasm, may be contained in their afferent nerve supplies. Just how this process of concentration or symbolizing obtains its basis in the grey matter no one knows, but indications newly derived suggest that neurokinetic stresses or strains, active neurokinesis, in short, rather than any imaginable kind of mechanical traces or vestigia in the neuroplasm (which is at least 80 per cent. water) are its immediate "physical basis," or energy-concomitant.

Fourteen years ago and more Sherrington published⁴ a research-based opinion that "the reverberation from the trunk, limbs, and viscera counts for relatively little, even in the primitive emotions of the dog, as compared with the cerebral reverberation to which is adjunct the psychical component of emotional reaction," and recently Cannon,⁵ in a timely article, like the rest of us, has agreed with him. No one whom I, for one, know of lays stress either on the necessity of an immediate flow of neurility from the environment for the action of the vast intricacies of cortical nerve knots; or on the permanence of the symbolism exhibited by these complicated nerve knots. They represent the body "even in the primitive emotions of the dog, and represent it adequately because of the perfection of their symbolic structure and function, but they perhaps would not represent the body for any purpose, volitional, cognitional, or affective, for a long period after the body had been severed from them. Even if these cerebral centers did continue to represent more or less adequately feeling and emotion involving normally the active somatic parts it would not cast out of our psychophysiology as a nonentity the human body or its inherent necessity in the evolution and actuation and apotheosis of the human personality. It would mean, rather, that there is some mechanism in the head, beyond the cutting-off place, transcendently more efficient than the mere neurologist can explain, in that it not only symbolizes all the somatic intricacies of motion in tridimensional space but also the subtle meanings and intentions and motivations of the soul itself.

On the other hand, things neurologic are too com-

plex and too interinvolved at present to make it quite fair to venture to compare directly normal and abnormal conditions, to presume, in short, that, because the "cerebral reverberation" continued to "reverberate," à la Sherrington, Cannon, et al., after the cat's brain was neurally separated from the cat's body, that the puissant movements, molecular and molar, of that cat's body have in the normal cat little to do with the emotion. To be sure, such an attitude is implied and not made explicit by these new physiologic animists. For our present argument it obviously is quite essential, however, that we call to mind that continually and permanently the real, that is the normal, frisky, happy cat, has an intricate flood of kinesthetic neurokinesis pouring into his spinal grey and upward into the cortex continually, invariably, and inevitably.

Philosophically, of course, this kinesthetic flood actually represents the sanction of the conception and birth of the individual, for only through the body and its attitudes toward its environment does the personality aspire (Paracelsus), and finally, more or less, attain its unique and worthy individuality. And the mechanists can not escape this point of view; nor the animists.

As elsewhere¹⁸ I have set forth, however feebly, this wholly adequate mechanism of always living matter, the world-evolution's magnus opus, is the human cortex cerebri. One might, if one could, wax eloquent over its prodigious complexity, its intricacy of neuronal pathway, its billions of perplexing neurones, but what would be the use after all? This would require counting and other difficult histological research which no competent one at present seems bent on performing, although, like the question of personal immortality for example, it is perhaps one of the questions of quite maximal human interest. The histologists, however, are most of them anatomists only, "nor look before nor after," and do not heed the call of the mind. In this indifference lies one's sanction in part for using at will the data which actually are at hand for the furtherance of psychology as a science of behavior.

In recent years at least we owe to William McDougall the restatement²² of an old notion that the brain is a reservoir of energy derived in part from the active organism and in part from the environment. I firmly believe that this, so far as the cortex is concerned, is not a metaphor or a simile but in great probability a scientific fact. Somehow it sounds right, and from the most recent notions as to the nature of the memory "traces," the "vestigia" of experiences, habit pathways, etc., it looks right also. Moreover, the potential connections of the cortex with everything else on earth in one way or another, both inside and outside our bodies, make it seem right altogether. Here are the muscles and the glands and the vegetative contractile net and the whole energetic environment more or less symbolized and integrated and represented for mental concomitance. Just as the autonomic ganglia of three classes represent a reservoir of energy, of neurokinesis, for nervous use in the vegetative mechanism all over the body; and just as the spinal grey and the numerous cells in the white tracts of the cord represent a reservoir of energy for actuating the voluntary musculature and, through the autonomic system, the vegetative musculature in part; and just as the bulbar centers and the cerebellum represent a reservoir of energy for another and more complex set of functions, so the trifold great cortex is a reservoir of neurokinesis for truly

voluntary (that is inhibitory) movement proper and for all integrations which involve (because of their extreme complexity) the lower circuits of bulb and cerebellum, of spinal grey, and of the autonomic. It is not possible to understand the innervation of behavior in any way far different from this on this threshold of 1915, Parmelee" to the contrary notwithstanding. The lower and shorter and more vegetative circuits of neurility each affects upward all those above it; but the control, the restraint, the inhibition is in the opposite direction, namely from above downward. Actuation, then, is integrated and coordinated primarily close to the mechanism which furnishes all the energy, in the abdomen and secondarily further up; while, on the other hand, control lies in the more human sphere, far as possible from the animal belly, in the neopallium.

Bolton's important researches⁶ on the cortical layers in man give explication to what before was more of a vague mystery. The accompanying illus-

Section of human cerebral cortex, to suggest especially the immense complexity of the neuronal relations (methods of Weigert and Golgi): C.Z., clear zone having no nerve fibers; M.P., Exner's plexus in the molecular layer; A.Str., ambiguous cell stratum; Subm.P., submolecular plexus; Gt.P.P., great pyramidal plexus; Pol.P., polymorphic plexus; W., white matter. (Andriezen.)

tration amply suggests the cortex's adequacy in the abstract; let us mention a few of Bolton's familiar notions for some particulars.

The "inner cell-lamina (polymorphic flexus) develops first and has attained three-fourths of its adult depth at the sixth fetal month; it is of constant thickness, is well developed in the least intelligent mammalia, and is little different from usual in the more ordinary grades of amentia. This layer of the cortex contains cells of several different forms, Golgi cells, multipolar cells, and the mysterious cells of Martinotti whose neurites, perhaps it is important to note, conduct toward the middle or granular layer, or outward and not inward. This is what is nowadays properly called the archipallium and sometimes the "paleoencephalon." With little present doubt, it represents the ultimate in-

tegrations of the *impulsive* aspects of the individual in his relations to his ever-changing environment—instinctive, "original," emotional.

The inner fiber layer consists in part of medullated neurites horizontal in position with the large triangular cells of Meynert or of Betz (in the Rolandic area) scattered through it. It is otherwise termed the great pyramidal plexus with Baillarger's inner band. This lamina develops at about the sixth fetal month.

The middle cell-layer or "granular" lamina consists largely of small pyramidal cells (with round nuclei) but with many multipolar cells, some small and some large. It is called a sensory or afferent coordinator. It is about half finished in its gross structure about the sixth month intrauterine.

The outer cell-lamina and the outer fiber-lamina ("Exner's plexus") show themselves in a way to be somewhat fundamentally different in functional respects from the layers beneath them. The latter, the "molecular layer," consists of the medullated neurites of multipolar "cells of Cajal" running parallel to the pia mater, many dendrites of cells below, together with scattered neuroglia cells; it appears to develop very early.

The outer cell-lamina, including "Baillarger's outer band," and otherwise called the submolecular plexus, consists of large, medium, and small pyramidal nerve cells, the largest being innermost and the smallest outermost, their neurites extending gradually inward to the inner fiber layer, while their dendrites arise in the plexus of Exner without. This layer develops slowly after birth until in adults of average intelligence it is thicker than the entire remainder of the cortex. It is the last layer of the cortex to develop and the first to degenerate in involution whether from old age or from disease, especially terminal dementia. In the various degrees of amentia (feeble-mindedness) its depth as well as its complexity seem to be in direct ratio to the phylenic scale.

All this, of course, is more or less familiar information summarized here only for the reader's convenience of recall. The functional opposition and developmental contrast between the inner cell lamina and the outer cannot fail to be obvious. Indeed the latest of the world's text books of physiology, that of Bainbridge and Menzies⁷ notes the matter thus: "A convenient modification of this description is to speak of the layers in their relation to the middle cell lamina or layer of granules. This arrangement gives (1) a supragranular layer, consisting of a fiber lamina and a cell lamina; (2) the granule layer itself, and (3) an infragranular layer, consisting of a fiber lamina and a cell lamina." According to Bolton⁸ the granular middle layer receives the afferent impulses and associates them with the laminæ below and above. Our illustration shows the intricacy of the give-and-take to and fro of each of these cortical layers with the others, commensurate with every psychophysical fact of living with every emotion.

Now, putting together the data set forth above and these facts about the cortex from the histologists, "what," in the slang of a day not long passed, "is the answer?" Perfectly aware, as I am, how many guesses have been made, how many are called and how few are chosen, still it remains an irresistible personal conclusion to our premises (the major set forth at length above and the minor later, from the histologists and embryologists)

that here are ample integrative plexuses for the two-phased phenomena of feeling, respectively impulse and its restraint, represented afferently respectively by the subconscious actuating kinesthesia and by the potentially conscious kinesthesia which is inhibitory.

Here, in the triple cortex (but not here alone, it is likely) is the adequate integrating mechanism for that particular balance with which especially feeling is concerned, a balance with several common characters. We certainly need not take valuable space to demonstrate how universal is this balance-principle in organic activity, but it is enough to call attention to the fact and its importance for the understanding of things. Every month, now-a-days, almost, some new example of the numerous physiologic balances is revealed or explained. It is the way life in organisms is carried on and made to fit continually the ever-changing environmental conditions—vasodilation and vasoconstriction; anabolism and catabolism; acidity and alkalinity; sympathetic and craniosacral; flexion and extension; toxin and antitoxin; thermogenesis and thermolysis; actuation and inhibition; and the rest, so that one is reminded of the wisdom of Emerson in a famous essay. Just in proportion as science works out this principle in the neurology of behavior will sundry roily matters of psychology clarify; and here is a "document in evidence" thereof.

It appears, then, that energy, kinesthesia, coming in part from the catabolizing and hence ever-moving body and in part from the ever-changing environment, floods into the great cortex, having been distributed thereto in some mode as yet undefined by the thalamus. By the ultimate and supreme marvel of experience, this neurokinesis, representing the bodily nexus between soul and its environment, is concomitant temporarily to the stream of mind and the dual intentions of the personality, vegetative and purposive, respectively. An aspect of this mental stream is feeling, and the actual feeling-experience of any moment is a balance between impulse and its restraint. The lower, archipallic, intricacies of the great cortex probably represent the impulses, and the upper, neopallic, layers the inhibitions by which alone these impulses are humanized. Here, I repeat, and, so far as known, here alone, is adequate mechanism for this two-fold symbolism of an almost infinitely complex body behaving in a manner almost infinitely complex toward an infinite environment.

Perhaps nowhere else so reasonably as in this two-fold layer of integrating and associating neurones is the psychophysiologic process of submergence so well possible. In the conditions we are considering (pleasant and unpleasant feelings, impulsive and restrained respectively) there seems indeed to be tendency to submergence both of the psychological aspect and of the physiological. The unpleasantness of the affective inhibition as well as its physiologic difficulty both lessen with use and perhaps with age without use. Applied to practical education of our behavior, we learn more or less completely to restrain our emotions and feelings, the process becomes more or less habitual, and the unpleasantness less in some instances and some emotions at least. This process in neural terms probably corresponds to the development of yet closer association between the archipallium and the neopallium, the two losing somewhat of their proper physiologic opposition—an artificial and, as it were, biologically speaking, an abnormal process, a

sophistication of animal life. Thus we see, as was said at first, a double sort of submergence—figuratively, a submergence of unpleasantness in an habituated subconsciousness, and literally, a submergence of motor control from the neopallium into the deeper layers of the cortex, the archipallium.

When these submergences have taken place it is obvious that the emotion or feeling has lost its proper physiologic nature, and no one must expect to find any director "principle" than we have tried to indicate of its somatic representation. As has been pointed out so often (e.g. "The Emotion of Joy"¹⁵) if we would see the feelings and emotions in their biologic purity, which alone is reducible to law, we must observe them in the brutes, in idiots or in imbeciles, in savages, or in such young children as are not yet sophisticated. We are compelled to urge this principle again and again because convinced that it is a fundamental matter in the neurology of affection. Habituation elsewhere is acknowledged preeminent, and no reason appears why it should be otherwise here.

This process of submergence has important theoretic value, but it likewise has far-reaching personal and social effects in human (perhaps in brute) behavior. It explains for one thing much of the *continuance* and the recurrence of asceticism, hermitism, denial in every extensive and continuous form among rational human beings with an average degree of impulse in their personalities. Without reference to the conditions among the Oriental religionists or in the monasteries of Europe centuries ago, we can see that the process was carried out among our own ancestors here in America:

"There exiles were formed in a whimsical mold,
And were awed by their priests like the Hebrews of old,
Disclaimed all pretense of jesting and laughter,
And sighed their lives through to be happy hereafter.

On a crown immaterial their hopes were intent,
They looked toward Zion wherever they went,
Did all things in hope of a future reward,
And worried mankind for the sake of the Lord."

—Freneau, circa 1750.

Physiologically, no one is going to believe that it is literally true that they "sighed their lives through" even "to be happy hereafter," any more than that they "worried mankind for the sake of the Lord." Their life-long sighing was certainly an extremely attenuated emotional state and didn't really prevent a fairly happy life full of novelty, of impulse and simple human joys, on which man's best contentment always rests. Their denial lost them some pleasure without a doubt (they certainly were not hedonists either theoretically or practically), but it quite failed, we may be sure, to inflict upon their long and busy lives that chronic unpleasantness denial in the abstract implies. In the children and adolescents the compelled inhibitions undoubtedly produced their physiological effects of unhappiness and discontent, but that habituation and submergence should have failed to greatly mollify this into a pretense or even into a mildly euphonic feeling of satisfaction it is impossible to believe. The same conditions apply to all chronic forms of arceticism, celibacy, and even to those more domestic kinds of denial (far more common and so quite as important) seen so strong in many of our blessed womenkind. The principle is worth urging, for it constitutes what is an apparent exception, but is not a real one, to the theory of feeling. The process of submergence, we may be

sure, does not alter materially the basal innervation of the emotions evolved in the developing nervous system.

VII. Summary.—Every tentative suggestion of a neurologic theory of behavior emits its own defiance, actually invites disproof, and so in a way furnishes its own necessary sanction as a contribution to the science of behavior.

For scientific technical purposes, the conceptual division of emotional behavior potentially into eighty or more feelings and emotions perhaps should be abandoned as only traditional, thus clearing the way for adequate study of the complex basal oppositions which biologically underlie all of these shades of feeling, the chief of which oppositions is that between (vegetative) impulse and (personal) control.

It is an adequate thesis (for proof or disproof) that the physical energy-aspect of feeling consists especially of numerous sets of kinesthetic neurokinetic impulses or strains which continually relate all layers of the great cortex to its ever-unique effective environment (whether outside the body or within it); the conscious inhibitory phase of the kinesthesia representing originally, in the infant, the feeling unpleasant in tone, and its subconscious actuating phase the pleasant emotion.

The actuation of movement, bodily and thorough mental, in the normal, unfatigued, and naïve individual, is the primal and enduring delight of all his experience.

In such a personality the inherent impulse to movement in space and in time seems to be represented neurally by the actuating phase of kinesthesia pleasant in tone whenever it rises out of "the subconscious."

In such a personality, too, the human restraint of impulsive movement in emotion seems to be represented by the unpleasantly conscious inhibitory phase of kinesthesia.

Organic evolution at heart is an ever-complexifying process of control over impulse.

In the triple intricacies of the great cortex is the only adequate integrating mechanism for that particular physiologic balance (here between pleasant actuation and unpleasant inhibition) which is concomitant on the usual symbolic plan to feeling.

As the child develops its personality properly human, a double kind of submergence seems to occur: figuratively, a submergence of unpleasantness in some cases into an habituated subconsciousness, and literally, perhaps, a submergence of neuronal motor control from the "neopallium" into the deeper layers of the cortex, the "archipallium." This universal process in no way invalidates the kinesthetic theory of feeling, since it leaves undisturbed the original primary influences on the autonomic and spinal greys as well as the secondary resultants therefrom into the cortex by way of the distributing thalamus.

PHENOMENA RESULTANT UPON FATIGUE AND SHOCK OF THE CENTRAL NERVOUS SYSTEM OBSERVED AT THE FRONT IN FRANCE.*

By E. MURRAY AUER, M.D.,

PHILADELPHIA, PA.

(LATE OF THE 23RD GENERAL HOSPITAL, B.E.F., FRANCE.)

THE manifestations of disordered function of the central nervous system resultant upon fatigue and shock occurring in the present war are of uncommon interest, having as they do for their etiology a more or less common factor, *i.e.* "a mine explosion" producing its varying effects upon the number involved, and because of their great variety, illustrate strongly the matter of "the individual equation" in reaction and resistance to outside influences.

The functional nervous and mental disorders studied included those resulting from the general fatigue of duty and long marches, exposure, loss of sleep, terror, and "shock," which latter cases depended upon the activity along the firing line such as "mine explosions," charges, and shell explosions in the immediate vicinity of the individual without causing any apparent physical trauma.

The symptomatology occurring as a result of these traumatic influences included disordered activity of the psychic, special sense, sensory, and motor elements, invariably in combination with one phenomenon of disordered function accentuated.

As a result of severe shock were seen states of hyper- and hypo-mental activity; the former characterized by increased motor and psychical activity, one case in particular showing the motor activity, playfulness, grimacing, flight of ideas, distractibility and rhyming of an acute mania. In his ravings the Iron Cross, Red Cross Division, and commands played no little part. The latter cases were characterized by stupor of varying degrees of profundity. In the most profound stupors there was no response to stimulation. The pupils were usually dilated and mobile. There was a certain amount of rigidity of the limbs, which did not increase on movement. The deep reflexes were very active but there was no Babinski; in one case there was abortive ankle clonus. In the milder cases the patients responded to most simple commands but

were markedly apathetic and indifferent to their surroundings. In none of the cases were there any urinary disturbances or difficulty in swallowing. These cases were usually the result of severe shelling, burial, or other severe psychical trauma; one case of mine occurred in a boy of 19, three days under heavy fire, who, after being threatened by his sergeant with court martial for sleeping on sentry, was for 10 days in a stuporous condition, as was similarly another who had witnessed his chum blown to pieces. On their recovery they were usually able to give an account of the psychical trauma productive of their condition. The duration of the stupor in the eight cases admitted to my ward ranged from 2 to 11 days, having existed from 1 to 3 days before their admission. Recovery was usually gradual, the cases having invariably been sent on before complete recovery. The terrified expression, crouching, starting, staring wildly when spoken to could not but impress one that the patient was still living through his terrifying experience. One man with profound stupor rose in his bed during the night, recited in a one-sided conversation his entire experience of a charge and burial and relapsed into his stuporous state. The following morning when questioned, he could not recall the incident. Recovery was usually marked by headaches, tremor, trench dreams, and in one case, mutism for three days, on the mornings of which days he was with little effort persuaded to speak, but the following morning he lapsed into his previous state.

Occurring after shock, as a result of which the patient may or may not have been rendered unconscious, were seen cases of marked tremor and shaking of which the following case is an excellent example: The patient was buried in a mine explosion at Hooze July 19, and on August 9, at Hill 60. Neither time was he unconscious, but he was badly frightened and his arms and legs shook. On July 19 a mine blew up the trench and he was partially buried and thought himself killed, but he struggled out of the debris and dashed on into the taken trenches, which were under heavy bombardment for eight hours. In the counter attack he was badly frightened, his eyes closed, his head and limbs shook and he had a superficial sharp shooting frontal headache. On August 9, at Hill 60, while building a parapet under heavy fire, a piece of parapet accidentally fell, striking him in the back and knocking him down. He was not rendered unconscious but the shaking and headache began again with greater severity. On examination he had a coarse irregular side-to-side movement of the head and a coarse, irregular tremor of both hands and legs. During an attempt to write the shaking of the head became worse and under observation all tremors were accentuated. He stated that his lower limbs felt dead at times; that he had hot and cold flashes, perspired easily, and had night frights. There was no contracture of the visual fields or organic neurological findings. He had superficial, sharp, shooting, frontal headache with boring pain in the back of the eyes. The tremors usually were confined to the arms, but also at times involved the lower limbs and more rarely the head. Tremor of the head was a side-to-side movement or a nodding of the head. Its duration varied from a few hours to several days or weeks after the injury, as in the case of one soldier who, bowled over by the impulse of a trench mortar and badly frightened, shook for a half hour; whereas three

*Read before the Philadelphia Neurological Society, March 24, 1916.

weeks later after a night fright, from which he awakened with his nerves all "drawn up," he had tremors for four days.

Disturbances of memory from simple forgetfulness to lapse of unconsciousness were not uncommon following exhaustion and fright. The amnesias occurring after psychical shock were of sudden onset and confined to a definite period. They were of varying duration from a few moments to a few days, as for example the soldier who at the beginning of a bombardment lost himself, ran from his machine gun up and down the trench, until a sharp order from his officer brought him to himself; another who stated that at Loos he was carried along in a charge but knew nothing of it, and who, at the beginning of a bombardment, dashed from his trench over six traverses and was brought to himself by falling and bumping his head; and lastly one soldier who, after a shell explosion, on coming to, found himself walking along a lane. A man, operated on for the removal of shrapnel from the knee, on recovering from the anesthetic, thought himself back in the trenches, talked excitedly of Germans and guns, became violent, moved his cupboard about, thinking it a machine gun and pointing it at his enemies. This state lasted three days, when, after a sleep of 12 hours, induced by veronal, he awakened rational. He had no knowledge of this period other than the incident of the machine gun. Another patient suffering from extreme nervousness following a scalp wound, was lying out of doors at the Base when a storm came up and at the first peal of thunder he dashed to the nearest tree, where he crouched, trembling. Shortly after he came to himself and returned to the ward. In the majority of cases, the amnesia was distinctly retrograde in type but in others following the shock of mine explosion it was retro-antegrade.

Exhibiting well the rôle of external affairs in precipitating mental conditions and the part they play in their symptomatology were two cases of dementia precox, unquestionably affected before the war. One in particular who, together with an attempt to explain the evolution of the European races along the ideas of ethereal wave lengths and the law of action and reaction, was, at the time I saw him, on his way to set Lord Kitchener "right" about the war; the other, who was possessed with many army experiences of a persecutory nature, showed the circumstantiality, irrelevance, looseness of thought connection, tendency to systematization of a paranoid type of dementia precox. One moron was returned because he persisted in shooting the men of his own side in the trenches ahead. He showed marked mental deficiency.

Inability to sleep was either partial or total. Many patients presenting symptoms of neurasthenia were unable to get to sleep until early hours of the morning for no apparent reason than because of the sound of their heart beating, or as stated, "I just cannot go to sleep." Others suffering from severe psychical trauma could not sleep for nights, but as the subjects were all young the greatest disturbance lay not so much in their inability to sleep as in the horrible trench dreams, night frights, and somnambulistic periods suffered by the majority of these cases. One became quite accustomed to seeing patients duck beneath their pillows, rise from their bed weeping and trembling or shouting loudly and at times, as in the cases mentioned, recounting some horrible experience. The night starts were very interesting, as some awakened with terror

bathed in perspiration but recalled no dreams; others dreamed of being pursued by Germans with bayonets, of being called to attention and unable to find their clothes, of a suffocating feeling across the chest, of losing the trench in a fog and unable to get back, etc. One nightmare in particular was of interest. This soldier had a recurrence of a nightmare of his childhood, which was that of seeing a dark woman descending a stair toward him, carrying a dagger. She was the Medea of which there was a picture in his home. These patients awakened startled from their sleep by the slightest stimulation.

Occurring from the continual exertion of duty, or following some illness or psychical trauma, were many cases of neurasthenia differing not essentially in their symptomatology from those observed in general practice. Those of gradual onset related a developing fatigue, inability to concentrate, headache, poor appetite, inability to sleep, etc. Those occurring after trauma were more in the nature of severe pains in different parts of the body, insomnia, etc. Patients of this group were for the greater part mentally depressed, although in good physical condition. Headache was the symptom of most common occurrence. Those following trauma (shock) were most generally pains of sharp shooting character, throbbing or pounding, superficial in a few cases, though most commonly deep, through the frontal and parietal regions with heavy or sharp shooting pains in the back of the eyeball. The patient invariably awakened in the morning with this pain which improved as the day progressed, but generally became worse at night. In but few cases did these headaches prevent the patient from going to sleep. The headache occurred either immediately or within an average of 24 hours after the trauma. The pain later became of a dull, heavy pressure type, changing its location frequently to the crown or occipital portion of the head. In one case it had the character of a tight band over the temples and supraorbital ridge. Movement of the eyes increased the pain in the eyeballs and any excitement greatly increased the headaches.

Of the central or psychical pains, those along the spine were most frequent, occurring usually in the region of the neck but more commonly about the sacrum. The painful areas were of fairly definite outline and followed no nerve distribution. Not infrequently in the beginning they were of a sharp shooting nature up and down the spine, which later settled as a dull heavy pain over the sacral region. Associated with the many complaints of tachycardia and cardiac arrhythmia was occasionally found pain of a knife-sticking character over the heart or a painful beating which made the whole body move, throbbed in the ears, and kept the patients awake at night; without any organic changes one frequently heard of shooting pains after emotion that interrupted breathing or of a feeling of weight that interfered with breathing. Pain through the stomach and bowels of no demonstrable origin, was not uncommon. In many of these cases, excluding those following gas poisoning, the patient complained of sharp shooting pain in the pit of the stomach, belching of gas, and acid eructation, all worse under fire or emotion. In the bowels the pain was usually of a griping nature, or a dragging sensation and it was most frequently located at the cecum. On palpation of the abdomen of these patients their reaction was remarkably greater

than the amount of possible pain caused warranted. In one instance only was pain along the urinary tract observed and this was in the urethra, which was extremely hyperesthetic to the passing of a sound. In a few cases in which the pain in the hips might have been considered as sciatica, Lesague's sign was absent. These patients usually awakened in the morning weary and unrefreshed, so short of breath and weak that they could barely walk. They were fault-finding, irritable and excitable, emotional and depressed. One individual was so depressed he thought he was going to lose his reason, and at times left his rifle unloaded to prevent suicide. The element of fear or anxiety was relatively uncommon considering the wealth of fear-producing stimuli, but in the severe neuropathic cases one encountered a feeling of incompetence, of doing something wrong, and fear of being shot for doing something wrong, a premonition of some impending danger, that something might arise in which he would fail, a fear of going to sleep lest he should not awaken. After a mine explosion or heavy bombardment the dread of returning to the trenches and fear of being hit was overweighted and conquered by the fear of loss of confidence or ridicule of their fellowmen, but withal frequently at the sound of the first shell they would lose control of themselves and, seized by an uncontrollable impulse of self-preservation, would run and crouch trembling in the dirt. One patient, denying any fear of being hit under heavy shelling, was possessed with a barely controllable longing to get out of the din, and on sentry duty had the sensation of someone being about and would challenge or be seized with an impulse to run. These anxieties when centered in self caused distressing fear as to the possibility of the heart ceasing to beat, or the blocking of food in the stomach or bowels, etc.

Difficulty of passing urine in the presence of others was a common occurrence. Following psychical trauma involuntary movement of the bowels and bladder was noticed, and nocturnal enuresis often recurred. Retention of urine was met with in only two instances, for periods of 8 and 12 hours. An irritable weakness of the sexual apparatus as evinced by nocturnal emissions was seen in a very few cases, occurring in one instance whenever the individual, a strong robust butcher boy, went to sleep, day or night. On awakening he was fatigued, depressed, and very emotional. In only one instance was there nocturnal emissions associated with erotic dreams, and these last were not constant.

Vasomotor disturbances proved to be most distressing symptoms, and had a wide range, from the transitory hyperemia of the face to the continuous feeling of heat and profuse perspiration or even cold, as in one patient, who complained that he was always cold, even on the march when others perspired, and when excited he became chilled and his scrotum drew up tightly. Under the slightest excitement these phenomena became aggravated, even the briefest examination causing pronounced hyperemia, elevation of the peripheral temperature, and profuse perspiration in many instances, while a sudden command so intensified the condition as to make the individual weak and incapacitated. Often these vasomotor phenomena accompanied the night frights and trench dreams suffered by these patients, and they awakened trembling, flushed, and bathed in perspiration. Arterial pulsation could

easily be seen, and in one individual complaining of a pronounced fluttering sensation in the abdomen, marked throbbing of the abdominal aorta was observed.

Abnormal sensations, dysesthesia of Dejerine or parasthesia of Oppenheim were felt; but by far the most characteristic occurrence in these cases was of the nature of numbness, pin and needle prick, cold and hot flashes, twitchings, creepings, a feeling of tightness, a rocking sensation on going to sleep, a dripping inside over the heart, a feeling when walking about as though someone had hold of him, whereupon he became nervous, perspired, and felt weak, while the blood seemed to leave his head, making him dizzy, or to leave his limbs, making him too weak to stand. These abnormal sensations were most generally confined to the limbs and not infrequently associated with pain.

Among the neuropaths suffering from functional attacks the etiology was of greatest similarity. These attacks followed some violent emotion resulting from either a physical or psychical trauma, and after their onset recurred under varied emotions such as fright, an unpleasant command, a distressing letter, a sentimental piece of music heard at the Y. M. C. A., or doing night sentry.

The attacks were generally diurnal, but not uncommonly upon awakening terrified from a night fright or trench dream the individual suffered an attack. Dysesthesia frequently occurred previous to the onset of an attack, but there was no definite aura or cry. The men were usually conscious during the attack and subject to command or suggestion. Only one patient stated that he slightly bruised himself in falling, and another on a few occasions passed his urine. Following the attack the patients did not sleep, but frequently showed tremor and shaking of the arms, had various pains, and not uncommonly heavy pressure headaches. Occurring with these attacks one frequently found amnesic periods as in one lad who, at the age of 17, for seven days knew nothing after falling down a flight of stairs, at 20 years of age had an amnesic period of five days following a nightmare, at 21 years a similar period of two days, and after a recent charge knew nothing for four days.

Loss of motor power was of gradual onset, as in severe neurasthenia, or of acute onset following shock, usually of the nature of burial by a mine explosion or of a shell explosion in the immediate vicinity of the patient without apparent physical injury. These patients may have been only temporarily stunned, or may have been unconscious, but the disturbance of motor power was invariably of immediate onset and was of the nature of a monoplegia, paraplegia, or hemiplegia. In the former cases the condition lay not so much in an inability to use the members, as in an extreme fatigue resulting from the effort, and was associated with general fatigue, headache, etc., which was usually more marked on awaking in the morning. Objective sensory disturbances were not observed, although subjective complaints were common. The hysterical paralyses did not differ from those seen in civil life in that they were either flaccid or spastic, with or without contracture; and objective sensory disturbance following no root distribution were present in varying degrees. The reflexes in these cases were prompt, but equal. The superficial reflexes were unchanged, and plantar stimulation caused plantar flexion or no response. None of the cases showed any disturbance of function

of sexual power, bladder, or bowel except in one individual who had a retention of urine for eight hours with no sexual or bowel trouble.

Impairment of vision resulted from prolonged fatigue or a sudden shock. The former cases were invariably of the nature of a photophobia in either one or both eyes, resulting from direct mechanical irritation producing conjunctivitis, *i.e.* blurring of vision from the smoke, dirt in the eyes while buried, etc. In the severe cases of nervous exhaustion was frequently met the statement that the eyes fatigued easily, that there was a blurring in the vision and a burning pain back of the eyes that caused blinking, black spots before the eyes, etc. Frequently it was seen that those complaining of inability to see did not do so because of constantly keeping the eyes closed because of photophobia, as interestingly shown in a case in which the photophobia had its onset following a night start four weeks after the patient had been buried in a mine explosion; and when visited the morning after the night start he said that he could not see, but when the eyelids were opened his vision was unimpaired except for marked lacrymation. Amaurosis followed severe shock, as the result of which the patient may have been merely stunned or rendered unconscious and was of extremely variable duration, some being brief, as in one individual who, every time he was reprimanded or frightened under fire, lost the vision of both eyes for fifteen or twenty minutes; and another who, when exposed to cold, suffered transitory blindness; while others passed the limit of three weeks at the base and were transferred to England with no improvement.

Auditory disturbances were of a hyper- or hypo-sensitive nature. Many of the neurasthenic cases complained of hyperacusis of an objective and subjective nature, the former, in which ordinary sounds, such as motorbus noises, bugle calls, shell-ing, etc., were greatly intensified; and the latter of the nature of a tinnitus, of the heart beat sounding in the ears, etc. In none of the cases of auditory disturbance was there any disturbance or sensation about the ears, nystagmus, or unsteadiness of gait. The watch tick was or was not heard in proportion to the degree of deafness. Rinne's test was positive, and in Weber's test, if the involvement was unilateral the vibrations were detected in the hearing ear. Deafness of a transitory nature was very common, due to shell explosion in close proximity to the individual, who through the violence of the explosion may have been hurled to the ground. It was very commonly associated with mutism, and in those cases in which it as associated the condition was of greater duration.

Hesitancy and loss of speech were seen in several cases following shock, with or without loss of consciousness. Stammering occurred in cases of general fatigue after prolonged exposure, or following night starts, as in one individual who, on the eighth night after burial in a mine explosion, awakened startled and for three weeks, in association with other neuropathic manifestations, stammered. In two cases where stammering had existed before enlistment, the condition was markedly aggravated. The early stages of mutism were accompanied by other manifestations of shock, and attempts at phonation were accompanied by twitching of the lips and facial muscles and lacrymation; in two cases of mutism was found pharyngeal anesthesia with abolition of the palatal reflex. In all the cases of deaf mutism the speech returned first

and later the hearing in either one or both ears. The cases of partial loss of voice in which the patient spoke in a whisper were of the greatest persistency. In one case, seen at the Second London General Hospital, the condition had lasted for several months.

Excluding spasm of the orbicularis palpebrarum, so commonly associated with conjunctivitis, there was seen but one case presenting tic of the lower left face, which had its onset after the patient had been hurled to the ground by the force of shell explosion, productive of no apparent physical injury. Spasm or cramp of the muscles of both lower limbs was seen in one individual, a clerk in civil life, which apparently had its onset after a prolonged period of trench digging. There was in two cases of miners' nystagmus a decided aggravation in one and in the other a recurrence of the condition in these individuals who served as sappers in tunnel digging.

Inquiry into the early history of the cases studied met, without exception, in the discovery of earlier neurotic manifestations as noted. Impulsiveness, inclination for solitude, avoidance of strange company, reticence, sense of being observed, fear and timidity in conversation, easy excitability, palpitation, inclination to jump when on a height, a tendency to blush easily and being very uneasy under feminine observation; abnormal sensations, a fear of corners and entries, an uneasiness in crossing a bridge; self-consciousness, St. Vitus' dance, a feeling of hypnotic influence exerted over him by some people whom he cannot resist; fear of being crushed in a crowd, fear in the dark, and a sense of being followed, in response to which they would turn about, hasten their pace, or even break into a run; a sense of falling when going to sleep, talking in the sleep, night frights, nightmares, somnambulism, erotic dreams, nightly emissions, nocturnal enuresis, psychical stricture on passing urine in the presence of others, heart thumping in his ears, preventing him from going asleep, etc.

Physical examination of these cases showed nothing unusual other than stigmata of degeneration. In the neurological examination, anisocoria and hippus were the most constant eye findings; true, nystagmus was not observed, although nystagmoid movements were frequently seen; contracture of the visual field of either one or both eyes was relatively uncommon, occurring only in a few of the cases showing hysterical paralysis, in only one of which cases was there tubular vision. In all cases observed, including those of stupor, the eye reflexes responded to light and, when the patient could co-operate, in accommodation. Anesthesia of the conjunctiva was not found. Ophthalmic examinations made by Dr. Maghy were negative. Treatment of these cases, except for the immediate treatment of the symptoms, consisted in isolation, absolute rest, with corrective measures, and psychotherapy.

3319 WALNUT STREET

Swimming Pool Conjunctivitis.—Harry S. Gradle found an existing conjunctivitis among eighteen young adults, in the majority of whom the condition developed three days after swimming in a confined pool. Under ordinary conditions the disease lasts about three weeks. In no case was there an involvement of the cornea or irritation of the deeper structures of the eye. The condition was treated with 1 per cent. silver nitrate daily, and argyrol 10 per cent. three times a day or more.—*Illinois Medical Journal.*

ACETONURIA IN RELATION TO CONTAGIOUS DISEASES.

By STEPHEN H. BLODGETT, M.D.,

BOSTON, MASS.

FOR the past ten years I have given much time to investigating the various diseases and conditions in which pernicious vomiting accompanied by acetonuria (without glycosuria) is a marked symptom and to ascertaining whether these various diseases and conditions bear any relation to the condition I first described in 1906. I have in numerous papers reported the results of my investigations, which have proved that there is a common condition underlying the pernicious vomiting of pregnancy, cyclic vomiting in children, pernicious post-operative vomiting, and also some attacks of vomiting in adults. The fact that vomiting is frequently the first symptom complained of in the commonly so-called contagious diseases led me in the spring of 1915 to investigate the relation of this condition to acetonuria in these diseases. These investigations were carried on at the John C. Haynes Memorial Hospital (the contagious department of the Massachusetts Homeopathic Hospital). The series covered one hundred consecutive cases with the exception of a few cases occurring in infants. The work was conducted in the following manner: On admission to the hospital the history, as regards vomiting during the few previous days was recorded, also the conditions of the tonsils, in addition to the usual routine history. A sample of the urine in each case was sent daily to the hospital laboratory, and I was granted the privilege of making such tests as I wished.

One of the particular points I desired to clear up was how often the "sore spot" over the pancreas would be found in the cases of contagious diseases, accompanied by acetone in the urine. As an explanation regarding this "sore spot," I will quote from a former article of mine, "Acetonuria and Carbohydrate Starvation":* "Vomiting, as the most marked symptom, occurs frequently where there is acetone and often diacetic acid without sugar in the urine. These patients usually have, in the beginning of the disease, at any rate, a clear tongue, and the vomiting occurs irrespective of what food may have been ingested. In almost all cases there is a sore spot that can be found on deep pressure over the region of the pancreas. This spot can be distinguished from the abdominal muscular soreness that follows attacks of vomiting by the fact that it is only found on deep pressure, and is a spot, perhaps only two inches in diameter, over the pancreas, while the muscular soreness following vomiting is brought out by superficial pressure and is more or less general over the entire abdomen. In extreme cases patients will complain of pain in the left hypochondrium and tell you that it is deep in. This 'sore spot' is almost pathognomonic of this condition."

Returning to my subject, to prevent any suspicion of collusion or biased judgment, the investigations were made as follows: The history for each patient as regarded vomiting, the condition of the throat, and the temperature was placed on a history sheet by Dr. Clement, the house physician. In addition to this, a chart showing the condition of the throat of each patient at the time of admission was filled out and sent to the laboratory, and on this the re-

sults of the daily urinary examinations were placed. A specimen of urine from each patient was sent daily to the laboratory and the analysis made either by myself or by my assistant, or by both of us. The examination for the "sore spot" was made daily on each patient by Dr. Clement and recorded under each patient's name on a sheet of paper, which was kept in the doctor's possession. No one else was allowed to see it, and he never saw the results of the urinary analyses. Three months after the investigations were completed, the various records were "assembled." The history regarding vomiting, the daily conditions of the throat, the daily temperature, our daily laboratory reports regarding albumin and acetone, and Dr. Clement's daily record concerning the "sore spot" were placed on a single sheet (making a complete record of each case).

The results under these rigorous conditions were a surprise even to me and go to show that the "sore spot," to which for several years I have called attention in cases of acetonuria, is of considerable diagnostic value.

As the complete record of each case, if printed in full, would take an immense amount of space, I have, on the following chart, recorded as briefly as possible only the important items which seemed to have any bearing on the acetone. On the history chart of each case a daily drawing was made out, showing the condition of the tonsils until they became normal. Each specimen of urine was tested for albumin, but as the presence or absence of albumin proved not to bear any relation to the acetone, I have not included it on this chart. Our acetone test which we used was the Legal color test, and our gradation was as follows: Large amount, considerable, moderate, trace, slight trace, none. The color indicating the "large amount" was of such a deep red as to appear black; while the "slight trace" was an exceedingly pale amethyst color.

After the urine from any case had been free from acetone for three consecutive days, it was not examined for three days, then if free, not again for three days, and if still free, the case was recorded as finished so far as the acetone test was concerned.

I would add in passing that the acetone did not reappear in any case after having been absent for three consecutive days.

In the tabulated form above I give the results of my investigations of the series of one hundred cases which included: Scarlet fever, 54 cases; tonsillitis, 1; mumps, 1; erysipelas, 3; measles, 13; whooping-cough and measles, 1; diphtheria, 21; laryngeal diphtheria, 4; reports lost, 2; total, 100 cases.

Scarlet Fever.—Of the fifty-four cases of scarlet fever under consideration, ten cases should be omitted, as they had passed the acute stage, the disease not having been recognized until desquamation began when they were sent to the hospital. Of the remaining forty-four cases, there were twenty-nine with a record of vomiting immediately before or after admission; of these twenty-nine, twenty-seven had acetone in the urine and two cases (27 and 29) had none.

Of the cases having "no vomiting after admission" and one "vomiting not recorded," there were fifteen. Among these fifteen cases, thirteen patients had acetone in the urine and two (5 and 26) had none.

To summarize as regards the appearance of acetone in the urine and the "sore spot," leaving out the incomplete records: there were among the scarlet fever patients thirty-eight cases with acetone,

*New York Medical Journal, August, 1915.

four without (5, 26, 27, 29). Of these thirty-eight cases with acetone, there were thirty-five that had the "sore spot," and one (44) that had general abdominal tenderness and fluid in the abdominal cavity, and two with no "sore spot." Of the four patients having no acetone, none had the "sore spot."

SCARLET FEVER.

Case	Tonsils	Vomiting	Acetone*	Temperature*	Sore Spot*
1	Large and red	Before	21-24	21-29+	21-23

*The figures under Acetone and Sore Spot indicate the days of the month between which acetone or the "sore spot" was present.
The figures under Temperature indicate the dates between which the temperature was abnormal except where a (+) is placed against the final date, it means that at that date even, the temperature had not become normal, but no further record, so far as this investigation is concerned, was kept.

Measles.—Thirteen cases—No. 66 should manifestly be left out, leaving twelve cases for consideration. Of these, ten had nausea or vomiting immediately before or after admission. Of these ten cases, eight had acetone in the urine, and two no acetone (cases 61 and 68). There were two cases

before death. Of the eighteen cases remaining for consideration, eight had vomiting before or after admission; of these, seven had acetone and one no acetone. There were ten cases with no record of vomiting. Of these, five had acetone and five no acetone.

FIG. 1.—Cases 10 and 13.

(64 and 65) with no vomiting recorded. Both of these showed acetone in the urine, one of these (65) showed a trace on one day only, however.

In the twelve cases of measles, to summarize as regards the appearance of acetone and the "sore spot": there were two (61 and 68) that had no acetone but did have a record of pancreatic tenderness; the record in one case was "very slight if any," in the other "very slight." One case (65) showed acetone but no pancreatic tenderness; the record says "trace of acetone on one day."

FIG. 3.—Case 27.

To summarize regarding acetone in the urine and the "sore spot" relation in these seventeen cases of diphtheria: twelve had acetone in the urine and five no acetone. In the five cases showing no acetone there was no "sore spot," and in two of the twelve cases showing acetone no "sore spot" was found.

Laryngeal Diphtheria.—Four cases—Three patients had vomiting before or after admission—one no vomiting. The patient that had no vomiting showed only a trace of acetone and no "sore spot." Of the three vomiting cases, two had acetone and

As regards the relation of acetone and the "sore spot" in these four cases, three had acetone (one "a trace only"), and one no acetone.

Relation Between Acetone in the Urine and Vomiting.—Taking the entire list of one hundred cases, leaving out only those where the record was incomplete and those that, when admitted, were convalescent, there were eighty-one cases; out of these eighty-one cases, fifty-one had vomiting, and thirty no vomiting. Out of fifty-one vomiting cases, forty-five had acetone and six had no acetone. Out of the thirty no-vomiting cases, twenty-one had acetone and nine no acetone.

Relation Between Acetone in the Urine and the "Sore Spot."—Taking the entire list of one hundred cases, leaving out only those where the record was incomplete and those that when admitted were convalescent, there were seventy-five cases; out of these seventy-five cases there were sixty-one cases showing acetone. Fifty of these showed the "sore spot," seven had a record of general tenderness over the abdomen, and four no "sore spot." However, two of these cases showing no "sore spot" showed only a trace of acetone on one examination of the urine. There were fourteen cases showing no acetone; ten of these had no "sore spot," two "very slight," one "very slight if any," and one "general soreness, none over pancreas."

To show that the amount of acetone bore no relation to the temperature, I give on a small chart the temperature and acetone in cases 10 and 13. In one of these, it will be seen the acetone decreased while the temperature increased, and in the other the temperature decreased while the acetone increased. The acetone also had no connection with the severity of the case, as in case 14, the acetone decreased while the temperature increased until death occurred, and in case 27 there was no acetone at all, although the temperature remained high till death occurred. Perhaps case 55 will illustrate as well as any the fact that there was no relation between the amount of acetone each day and the amount of albumin.

I give in detailed form the record of case 1, which in its general characteristics was more or less similar to that of the other cases: Admitted April 21; tonsils large and fiery red, very much inflamed; vomited day before admission, not after admission.

Date	Temp.	Albumin.	Acetone	Throat	Sore Spot
April 21	103.2	Trace	Considerable		Present
22	104°	None	Moderate		Present
23	104.8°	None	Moderate		Present
24	103.2°	None	Slight trace		
25	101°	Very slight trace	None		
26	100°	None	None	Negative	
27	99°	None	None		
28	98.8°	None	None		
29	99°	None	None		

I would say now, in closing, that the close relation between the "sore spot" and the appearance of acetone in the urine, as shown in this paper, is the same relation that I found where acetonuria is present in the urine with vomiting in the non-contagious diseases. Reports of my investigations of this relation in non-contagious diseases were published in 1911 and since, but in no other previous investigations have my tests been carried out, as regards the "sore spot," so rigorously as at the present time.

THE ACUTE SURGICAL ABDOMEN.*

By THOMAS F. LANCER, M.D.,

NEW YORK.

VISITING SURGEON, ST. LAURENCE HOSPITAL. ASSOCIATE SURGEON, UNION HOSPITAL.

THIS paper is based on a recent series of unselected acute abdominal cases operated on by me at St. Laurence Hospital, most of them desperately ill, such as one finds coming into an emergency service by ambulance. I shall endeavor to make a special plea for the early recognition and prompt operative procedure in this class of cases.

The responsibilities in a given case are often great, since the life of a patient may depend upon the prompt decision of the question, shall the abdomen be opened or not? The risk of exploration is slight, and in many cases where the precise nature and origin of the lesion are in doubt and the patient exhibits signs of a serious intraabdominal condition, one is justified in operating.

The good results following early operation in this class of cases, together with the dangers and the hopelessness of interference when the patient is exhausted by the absorption of toxins, or by general peritonitis with intestinal paralysis, should be recognized by all.

The following is a classification of this series of 30 acute abdominal lesions: Group A—In 19 cases, or 63.3 per cent. of the total, the appendix was the offender; 8 of these had had one or more previous attacks.

In 6 cases the inflammatory process had not extended beyond the walls of the appendix, that is, they were operated upon early. There was nothing unusual about these 6 cases except the following:

No. 3. A policeman, aged 30, slight attack one year ago. On admission, temperature 101°, pulse 100, white blood count 14,800, polymorphonuclear count 79 per cent. Catarrhal appendix removed. Primary union. On the tenth day he developed a pulmonary embolism in the lower lobe from which he made an uneventful recovery.

No. 10. A multipara aged 42, weighing 250 pounds, with a very fat abdominal wall, was admitted with a diagnosis of cholecystitis. Temperature 101°, pulse 92, white blood count 16,000, polymorphonuclear count 81 per cent. A right rectus incision with its midpoint opposite the umbilicus, showed the gall-bladder and ducts apparently normal. An erect turgid appendix was removed.

In 10 cases of appendicitis the damage had extended beyond its origin, causing a local peritonitis with limiting adhesions. Among these were:

No. 5. A young woman aged 22, three months pregnant. On admission, temperature 101°, pulse 120, total white blood count 29,000, and 88 per cent. polymorphonuclears. Black gangrenous appendix removed, no odor to pus. Drainage instituted. This proved to be a *Bacillus pyocyaneus* infection.

No. 11. Was a girl 17 years of age, with a gangrenous appendix who developed a severe post-operative "black vomiting" which cleared up after repeated gastric lavage.

In 3 cases diffuse peritonitis had resulted from delay in submitting to operative interference.

No. 7. Was a boy 8 years of age, ill for several days and had the usual castor oil treatment at home. On admission, temperature 103°, pulse 126, total white blood count 31,800, polymorphonuclear count 84 per cent. Ruptured appendix removed. Free pus all through peritoneal cavity.

No. 13. A boy 5 years of age. Four days ill. On admission, temperature 102°, pulse 130, total white blood count 80,000 and polymorphonuclears 90 per

*Read before the New York Celtic Medical Society, January 20, 1916.

cent. Pathological condition similar to that in case No. 7.

No. 19. A young woman 20 years of age, had a perforated appendix with free pus and marked congestion of the visceral peritoneum. On admission, temperature 103.2°, pulse 128, white blood count 16,600, differential count 85 per cent polymorphonuclears.

Out of these 19 cases of appendicitis, only six were seen early, that is, before the infection had gone beyond the appendix.

Group B—In 5 of the total cases the uterine adnexa were at fault.

No. 26. Was a married woman, nullipara, aged 26. On admission, temperature 101°, pulse 100, white blood count 56,200, polymorphonuclear count 86 per cent. No history of menstrual irregularity or sudden severe pain. Physical examination disclosed a tender mass in right side of pelvis. No evidence of appreciable hemorrhage. Right rectus celiotomy showed a ruptured extrauterine pregnancy with an inflamed appendix attached to the mass. Both were removed and wound sutured without drainage.

No. 28. Unmarried girl 20 years of age, was admitted with signs simulating ectopic pregnancy. Temperature 100.8°, pulse 104, white blood count 39,600 and 74 per cent polymorphonuclears. On opening the abdomen considerable blood was found and the right ovary was cystic and ruptured. This was removed, together with the appendix.

Nos. 29 and 30. Were cases of pelvic peritonitis complicating purulent salpingitis. Celiotomy with drainage was done. Both made uninterrupted recoveries.

No. 27. Was a case of pelvic peritonitis, right ovarian abscess and suppurative appendicitis in a young married woman 22 years of age. She gave a history of a septic abortion two weeks previously. On admission, temperature 101.4, pulse 130, white blood count 47,600 and 85 per cent polymorphonuclears. Gangrenous appendix and necrotic ovary removed, free pus removed by wet sponges. Oiled silk cigarette drains placed in right iliac fossa and one vaginal drain placed in the cul-de-sac. Patient was discharged cured in four weeks, after a stormy convalescence.

Group C—In 3 cases the biliary passages were the site of the lesion.

No. 21. A multipara 50 years of age, was admitted with a normal pulse and temperature, white blood count 13,000 and 85 per cent polymorphonuclears. She complained of vomiting, pain and tenderness in the upper right quadrant of the abdomen and had a well marked cholemia. I performed a choledochostomy through the upper right rectus, removing a single large stone from the supraduodenal portion of the common duct and drained the same.

No. 22. A multipara 53 years of age, was admitted with a temperature of 101°, pulse 90, white blood count 24,400 and a polymorphonuclear count of 81 per cent. She had a hysterectomy done ten years ago. Always constipated. Three days before admission, she was awakened during the night by a severe abdominal pain accompanied by a chill and vomiting. On admission, pain, tenderness and rigidity were localized in the right upper quadrant. Celiotomy disclosed an empyema of the gall bladder in which was found a single oval stone acting as a ball-valve to the opening of the cystic duct. A cholecystostomy was done for drainage on account of the associated cholangitis.

No. 23. Was a multipara 53 years of age, with empyema of the gall bladder and no stones, due to infection and pressure by a carcinoma at the head of the pancreas. A cholecystostomy was done.

Group D—The fourth group consists of 3 acute operative cases.

No. 16. A boy 7 years of age, knocked down by a wagon one week prior to admission. Apparently well in the interval. A diagnosis of general peritonitis, probably due to a perforated appendix, was made. His abdomen was uniformly tender and boardlike in rigidity. There was repeated vomiting. A right rectus incision showed a normal appendix but free peritoneal pus. A further search disclosed a mass to the left of the umbilicus which proved to be an abscess between the layers of the mesentery of the small intestine.

The abscess had ruptured causing a diffuse peritonitis. The abscess cavity, pelvis and iliac fossæ were drained. The appendix was also removed.

No. 24. Subdiaphragmatic abscess of the left side, traumatic in origin. A widow 48 years of age, was struck on the left side of abdomen and thorax by an automobile. On admission, her pulse could not be counted at the wrist and her temperature was subnormal. She presented a clinical picture of profound shock. No blood in urine. Bowel movements that night were slightly blood-stained. White blood count 47,000 and 89 per cent polymorphonuclears. One week after admission she had well developed signs of fluid in the left pleural cavity. I resected the ninth rib in the mid-axillary line and found a large amount of sterile non-odorous blood-stained fluid. Temperature, pain and tenderness in the left side continued. White blood count reached 77,700 and polymorphonuclears 89 per cent. Aspiration showed chocolate colored fetid pus beneath the dome of the diaphragm on the left side. The original thoracotomy wound was enlarged and the tenth rib was resected adjoining the resection of the ninth rib. The pleural cavity had ceased draining and was walled off by adhesions. The diaphragm was exposed and opened and a large quantity of putrid pus was evacuated. Three large rubber tubes were introduced through the thoracic wound to the bottom of the cavity beneath the diaphragm and sutured in place.

No. 25. Was a case of diffuse peritonitis thirty hours after perforation of a duodenal ulcer. The patient a man 43 years of age, was seized by a sharp abdominal pain while cranking an automobile. A laparotomy with drainage cleared up his peritonitis and the patient was discharged from the hospital. He returned three months later with signs of malignant obstruction in the vicinity of the pylorus. Exploration disclosed an inoperable carcinoma as the cause of the obstruction. I performed an anterior gastroenterostomy, as the posterior route was found impracticable owing to the dense adhesions. The patient was discharged from the hospital three weeks later.

In following up these thirty cases there were two deaths subsequent to their discharge, No. 23 and No. 25 both being due to malignant disease.

Differential diagnosis—Fortunately most of the serious acute abdominal conditions demand laparotomy, so that the attending physician must especially bear in mind those lesions in which exploration of the abdomen would not only be unnecessary but harmful. These conditions are the following. (1) Referred pain in thoracic affections, especially in children. (2) Referred pain from spinal affections. (3) Visceral crises in tabes or in the erythema group. (4) Typhoid fever. (5) Acute gastroenteritis. (6) Acute dilatation of the stomach. (7) Pyelonephritis in childhood and during pregnancy. (8) Dietl's crises in floating kidney. (9) Inflammation of the abdominal portion of the vas deferens. (10) Angina sclerotica abdominis (Ortner's disease). The operating surgeon must eliminate the presence of these lesions before opening the abdomen.

Practical Remarks.—The leucocyte count has proved valuable, especially in cases with little or no elevation of temperature, low pulse rate and slight abdominal signs, as in many of these cases the increased total count or preponderance of polymorphonuclear cells in the differential count has been the only evidence of the seriousness of the lesion.

Cases No. 13, No. 24 and No. 26 had unusually high leucocyte counts, each being over 50,000. The taking of the blood and making the total white cell and differential counts should not delay the operation, as it requires but 15 to 20 minutes to obtain the figures and is done while the patient is being shaved and prepared for the operating room.

Appendicitis is the most common abdominal affection in young people and the most fruitful source

of peritoneal infection. These cases often give a history of recent indiscretion in diet which may confuse the attending physician in the early hours of the attack. In children perforation of the appendix takes place earlier than in adults and diffuse peritonitis with little or no adhesions is common, but fortunately they do well if given a chance. Rectal examination is a valuable diagnostic aid in children.

The diagnosis is the most essential factor in appendicitis as the proper treatment can then be instituted which is operative, since it is a surgical disease from its very inception. The pulse becoming gradually more accelerated means a local extension of the inflammation or systemic absorption. All appendicitis patients are considered emergency cases and operated upon as soon as practicable, as a few hours may be of vital moment in some instances. When operated at the proper time you may avoid a delayed convalescence, extension of infection, adhesions and subsequent intestinal obstruction, or a suppurating wound which may be followed by hernia.

It is advisable in women always to gain an idea of the pelvic condition if possible when the abdomen is open and the diagnosis questionable.

The incision that my colleague Dr. Merrigan and I have used for a number of years, is through the right rectus sheath, displacing the whole rectus muscle with its intact nerve supply outward from the median line. Its value lies in the fact that through this incision or its extension, we can explore the pelvis or gall bladder region, and that in so doing we do not deprive any of the abdominal muscles of their nerve supply, thus obviating a possible subsequent hernia due to muscular paralysis.

In closing I would like to emphasize, that a patient who has (1) abdominal muscular rigidity, (2) pain and tenderness, (3) a blood picture that shows a high total white cell count and a high percentage of polymorphonuclear cells in the differential count, or either one, that these constitute the "essential triad" for demanding operative exploration of the abdomen. The only exception would be in a case where the surgeon was sure that these signs were due to an acute salpingo-oophoritis which should be treated conservatively at the beginning.

2040 UNIVERSITY AVENUE

SARCOMA OF THE OVARY COMPLICATING THE PUERPERIUM.*

By GEORGE L. BRODHEAD, M.D.,

NEW YORK.

THE history of this case is of such unusual interest that we are reporting it to this section.

Mrs. F., primipara, age 18, negress, presented herself at the prenatal clinic of the Harlem Hospital on September 9, 1915. The history was negative, nothing abnormal was found in the abdominal examination, and on October 25, 1915, at term, the patient was delivered normally, of a living child, with moderate hemorrhage and no laceration. On the day following delivery, the condition was good, the temperature 100.2° F. On the second day following delivery the temperature was 101.4°, pulse 96, no complaint. On the third day following delivery the temperature rose to 102.5°, pulse 132, and the patient complained of pain and tenderness in the abdomen. The left side of the abdomen was soft and slightly tender, but there were marked tenderness and rigidity in the right inguinal and lumbar regions, and also in the epigastric and upper um-

bilical regions. The leucocytes were 17,000, the polynuclear count 88 per cent.—lymphocytes 12 per cent. On the fourth day the temperature rose to 103.2°, pulse 130; the tenderness and rigidity increased and vaginal examination showed some tenderness in the fornices. For the next seven days, until the day of operation, the temperature varied usually between 101° and 103°, and after the operation remained normal. Various diagnoses were made by the surgical staff, but finally on November 2, eight days after delivery, a mass could be palpated in the right lower quadrant; it was tender, elastic, and slightly movable, and a diagnosis of abdominal tumor was made. The blood count now showed leucocytes 21,000, polynuclear 74 per cent., and the urine showed a faint trace of albumin and a positive glucose reaction. The patient was transferred to the service of Dr. Haynes, who performed laparotomy, and found a sarcoma of the right ovary, measuring 15x8x6 cm., bluish in color, with greatly dilated veins. The patient made an uninterrupted recovery, and left the hospital in good condition.

The report of the pathologist, Dr. Gonzales, follows: Tissues: Specimen of ovarian tumor, size of a child's head, very soft in consistency, brownish red in color, smooth capsule, slightly lobulated, and showing fibrous bands. Cut section reddish granular in appearance with no surface markings. Microscopic section shows numerous spindle cells with fairly well stained nuclei and somewhat granular necrotic protoplasm, the tumor apparently outgrowing its blood supply. Vessels few and thrombosed. Cells are arranged around them in a radiating manner very like a perithelioma. Fibrous tissue very slight in amount. Diagnosis: Spindle-celled sarcoma.

The question naturally arises, "Should the other ovary, which was apparently normal, have been removed also?" Many operators believe that double ovariectomy should be performed, because of the danger of a similar lesion in the remaining ovary. In the early child-bearing period, however, when off-spring are greatly desired, we believe that the ovary which appears to be normal should be saved.

144 WEST FIFTY-EIGHTH STREET.

Medicolegal Notes.

Damages for Breach of Contract to Attend Accouchement.—In a suit against a physician for breach of contract it appeared that several weeks prior to Friday, the 14th day of September, 1912, the physician entered into a contract with the plaintiff's husband, for her benefit, to attend at her approaching accouchement, for a fee of \$20. About 10 P.M. on that day the plaintiff was attacked by what she supposed to be labor pains. A messenger was sent to the defendant, who was then six miles away at the home of another patient, then also about to be delivered of a child. The defendant could not leave the patient, so the messenger tried, but in vain, to get another physician. The patient the defendant was attending was not then delivered of the child, and continued to require his attention until about 6 P.M. next day. The plaintiff's child was not born until the night of the following Thursday, she having then obtained the services of another physician. There was some testimony of physicians that the plaintiff must have been mistaken in thinking she was suffering from labor pains when her husband sent for the defendant; that her pains must have been "false" instead of real labor pains, but that if false the pains could have been relieved by a physician. The plaintiff testified that she had had a number of children, that she knew by experience what labor pains were, and that had the defendant attended her on the night or morning after he was sent for she would have been delivered of the child within two or three hours. She suffered pains at intervals from Friday night until Thursday night. The jury found for the plaintiff and gave \$150 damages. Judgment for the plaintiff was affirmed on appeal, Stevens, J., dissenting on the ground that, admitting the contract and the breach thereof, the plaintiff had sustained only nominal damages, and the jury must have been influenced by the defendant's poverty, the ignorance of her rights by the defendant, according to the plaintiff's evidence, and the natural sympathy which everyone must feel for a woman in impending travail.—Hood versus Moffett, Mississippi Supreme Court, 69 So. 664.

THE THERAPEUTICS OF CANCER.

THE renewed interest in cancer which followed the discovery that malignant growths can be transplanted from one animal to another, has extended from the domain of experimental pathology to that of therapeutics, and no sooner is a report issued from the laboratory than the procedure is tried at the bedside. It is right that this should be so, provided only inoperable cases are chosen, for in our efforts to control this dreadful scourge nothing must be left undone; the immediate and blind application of a method, however, is not right. The attitude of the therapist toward the laboratory should be as critical as he can make it, in order that he may be in a position to select the most reliable results for his clinical investigations; an experiment, said a great investigator once, is not necessarily scientific because it has been performed on a rabbit. But even more important than this critical attitude should be one of endeavor to discover exactly what it is that the laboratory is trying to bring about. For example, while it has been discovered that mice can be immunized with normal mouse tissues against the inoculation of tumors, it has been expressly stated by those best qualified to know, that such treatment has no effect upon transplanted tumors already established; now as these are under relatively unfavorable conditions compared with spontaneous neoplasms, being composed of the cells of an animal other than that in which they are proliferating, while the latter consist of cells of the animal itself, it is evident that transplantable growths should be much more easily cured than spontaneous; and yet even these inoculable neoplasms cannot be healed at present. Nevertheless, many attempts have been made to cure spontaneous tumors in man, in spite of this distinction, by the injection of normal human tissues, generally in the form of extracts, although the laboratory has definitely explained that living and intact cells are necessary for the production of immunity; but not only have normal tissues been tried; emulsions of living tumor cells have been introduced, which, in several instances, have led to the production of new tumors at the point of inoculation.

All this is not so much the fault of the clinician, perhaps, as it is his misfortune, for he is no better able to judge between conflicting laboratory reports than the experimental pathologist would be to

choose between two rival therapeutic methods. On the other hand, pathologists do not differ so greatly in opinion as the contradictory nature of much of their writing would suggest; a great deal of the apparent disagreement is due to the fact that it was not realized in the first few years of cancer research that transplantable tumors vary remarkably in such characteristics as type of growth, susceptibility to immunity, etc., and that in some of them, even complete spontaneous disappearance is not an unusual occurrence in untreated animals. Fränkel and Fürer (*Wiener klin. Wochenschr.*, 1915, XXVIII, 1433, and 1916, XXIX, 63) have, therefore, performed a work of great value to both clinician and pathologist in reviewing some of these earlier conflicting findings in the light of our more recent knowledge. They have carefully investigated the question whether cell-free juices from the tumors of rats and mice have any immunizing or therapeutic action in these animals, and have found that they possess neither.

Their second paper is devoted to a discussion of the effect of foreign sera upon growing tumors, it having been assumed by various writers that the serum of a normal individual differs from that of the cancerous organism in the possession of some substance injurious to the cancer cell, or that it contains a ferment with the power of dissolving tumor cells. Fränkel and Fürer very wisely divorced themselves from all theory, and set themselves the task of finding out simply whether foreign serum would or would not influence the growth of transplantable neoplasms. Mice bearing carcinoma or sarcoma were inoculated intravenously one or more times with horse, goat, sheep, goose, rabbit, and guinea-pig serum, but in no case was the tumor definitely affected, although amounts of from one-fortieth to one-twentieth of the body weight were introduced. In a few of the animals the rate of proliferation was somewhat retarded; but a similar occurrence was noted in some of the untreated controls. The experiments have an important bearing upon the many attempts that have been made to influence new growths in the human subject by the injection of serum from adults or from infants, the procedure being based, in the latter instance, upon the false assumption that because infants do not have cancer, there must be some protective substance in their blood.

In conclusion, it is necessary to point out only that no authoritative cure of either transplantable or spontaneous neoplasms in animals has yet been published, even the selenium cure, from which so much was looked for in some quarters, having been proved a complete failure. In man, therefore, the surgeon still may, with more or less apparent justification, claim that the only hope of relief lies in early and complete surgical removal.

MEDICAL LIBRARIES FOR HOSPITALS.

A FEATURE of hospital work, which has hitherto received but cursory attention, is gradually coming into its own. The form of hospital library most familiar to us in the past is a room containing two or three bookcases of more or less obsolete pattern; these contain a few of the standard works on

practice and surgery—not the most recent imprints—a file of dusty hospital reports, several files of medical journals for the years 1880-1885, a medical dictionary about ten years old, and a general air of neglect. Those hospitals which made some effort to furnish reading, meaning fiction, for the patients, and they were usually hospitals where the sick were chronic in type, rather institutions than hospitals proper, added the old library stand-bys to their equipment. Marryat, Charles Reade, Cooper, Dickens, Thackeray and Scott, E. P. Roe, and Marie Correlli for the grown-ups, Louisa May Alcott, Henty, Alger, Oliver Optic, and the like if there were children, old copies of the 10 and 15-cent magazines, and various miscellaneous and well-worn volumes donated by individuals in impulsive moments. These heterogeneous collections of literature and what passed for it were under the nominal control sometimes of the resident physician, sometimes of the head nurse, sometimes of the pharmacist—in fact, of any official who was assumed to be able to spare enough time from his regular duties. Such a condition of affairs was of course hardly calculated to develop the true functions of a library, hence that institution often degenerated into a sort of a lounging room for internes by day and a trysting place for nurses by night.

Hospitals for the insane, however, have usually rather more effective libraries, it having long been recognized that their patients find diversion of a beneficial kind in books. Nearly all such libraries are in charge of a full-time librarian who sees that the books circulate and that the various classes of patients receive literature fairly appropriate to their capacities. It is from one of these, in fact, that a new order of things in hospital libraries is having its inception. Miss E. Kathleen Jones, librarian of the McLean Hospital at Waverly, Mass., has started a movement for interchange of ideas among hospital libraries, as a result of which the American Library Association has appointed a "Committee on Library Work in Hospitals and Charitable and Correctional Institutions." The work of this committee is to organize an "Institution Libraries League" for mutual help and it plans to publish monographs on subjects relating to this work from time to time.

In an article in *Modern Hospital* for October, 1915, Miss Jones calls attention to the usual haphazard way of running hospital libraries and also directs attention to the peculiar needs of libraries for insane hospitals. In the following issue of the same periodical Miss Meyers gives an interesting account of the history of medical libraries in hospitals in this country together with their present status. She says "the physicians and surgeons of the hospital staff need the literature of the day in all branches of medicine and surgery, and they need it while they are among patients." In the same periodical for December Miss Carey discusses the especial needs of libraries in State Hospitals. The education of the nurse in library work particularly as it relates to the means for interesting patients in reading and the appropriate distribution of literature to the mentally disordered, is

described by Miss Jones in the *American Journal of Insanity* for October, 1915.

Let us hope that these almost synchronous efforts to interest the profession in this branch of hospital management will bear fruit in the establishment of adequate libraries where the physicians can look up the details of an obscure question with some hope of obtaining modern views on the subject and where the interne can interest himself profitably during his evenings and Sundays on duty.

ROCKY MOUNTAIN SPOTTED FEVER.

FOURTEEN years of investigation have revealed some of the facts bearing upon the nature of the virus of Rocky Mountain spotted fever. Man, rhesus monkey, and at least six varieties of small wild rodents found in the Rocky Mountain region are susceptible to infection, while the larger domestic animals are generally immune. The virus is transmitted to susceptible animals, including man, by the bite of infected woodticks, recovery being followed by complete immunity. No other biting arachnid or other insect has been found capable of transmitting the virus. The transmission is not mechanical, since a tick once infected remains so, the virus multiplies in the tick, and the female transmits the virus to her progeny.

In Public Health Reports, March 3, 1916, L. D. Fricks, surgeon U. S. Public Health Service, describes recent investigations of the virus by himself and Drs. A. M. Stimson and R. R. Spencer. It was thought that because of the close clinical resemblance between Rocky Mountain spotted fever and typhus fever, and because of the discovery by Plotz of the *Bacillus typhi exanthematici*, that it would be worth while to study closely the different anaerobic bacilli which have been encountered during the researches instituted by Fricks and his colleagues.

The organisms recovered from spotted fever guinea-pigs resemble very closely morphologically and culturally the two strains recovered from typhus guinea-pigs by Hasseltine and Neill at the Hygienic Laboratory and the strain of *Bacillus typhi exanthematici* furnished by Plotz. On microscopical examination of spotted fever blood there appears to be some resemblance between these bodies and those described by Seidelin as having been found by him in yellow fever blood; and in view of the criticism of Seidelin's work made by Wenyon and Low who claim to have found similar bodies in normal guinea-pig blood, no definite conclusions can be drawn from the findings of Fricks and his co-workers.

Fricks, however, thinks that from the fact that these bodies on account of their morphological and tinctorial characteristics may be regarded as probably of protozoan nature, and because they have thus far been found only in blood from animals infected with spotted fever, the publication of their description at this time is justified, in order that other workers may be on the lookout for them, and that their relationship to Rocky Mountain spotted fever may be fully established or disproved.

THE MENINGOCOCCUS.

It has been surmised, indeed known for some time, that the meningococcus which caused cerebrospinal fever is of more than one type. Capt. A. W. M. Ellis, in a paper contributed to the *Journal of the Royal Army Medical Corps* for January, gives the classification of meningococci based on a group agglutination obtained with monovalent immune rabbit sera. His summary is as follows: (1) The causative agent of cerebrospinal fever, the meningococcus, is of at least two types. (2) These two types are as regards the one immune reaction tested, agglutination, absolutely independent. (3) In a study of forty-six strains of meningococci obtained from various sources all were of one or another of these two types. (4) Both types are widely distributed, having been found in each of six epidemic foci. They may occur with equal frequency. (5) Both types have been found in the nasopharynx of healthy carriers. (6) These two types have been designated types one and two. (7) In so far as evidence is available, type one has been more frequently the cause of the disease in the recent epidemics than has type two. In view of the wide distribution of the two types, both must, however, be held equally responsible as causative agents of cerebrospinal fever. (8) The organism described as type two is probably identical with the parameningococcus of Doptex. (9) It is suggested that, in the treatment of cerebrospinal fever better results might be obtained and more exact knowledge of the adequacy of serum treatment gained if monovalent horse serum of appropriate type, and therefore known to be active against the infecting organism, were employed in place of the polyvalent sera at present in use.

DEATH FROM HIGH EXPLOSIVE SHELLS.

FROM time to time there have come reports from the battle-fields of Europe that the explosion of the so-called "high-explosive shell" might cause death over a wide area and that some of the bodies are without the slightest indication of any wound. It has been believed that the changes in air pressure occurring suddenly and to a great degree, acted to cause death and an interesting confirmation of this theory is reported by Fauntleroy (*U. S. Naval Medical Bulletin*, January, 1916, p. 34). An aneroid barometer had been damaged by the explosion of a big shell three yards away from it. It was sent to a French engineer, who found that the levers had been forced into a certain abnormal position. He replaced them in the proper position and put the instrument in a bell-jar and exhausted it. When the pressure had been reduced to 410 mm. the levers assumed the position in which he had found them. The explosion had, therefore, caused a sudden depression of atmospheric pressure to the extent of 350 mm., corresponding to a dynamic pressure of about 10 tons to the square yard. Fauntleroy discusses the possibility that this sudden lowering of pressure may be similar in its effects to acute caisson disease and that bubbles of nitrogen may be liberated in the blood and cause death. He thinks it more plausible, however, to assume that the primary compression which occurs may easily cause death by the violent air impact delivered as a blow over one side of the body and especially over the heart and readily compressed abdomen, thus causing reflex actions that register themselves with fatal effect.

THE POLYSYLLABIC PHYSICIAN.

FROM time immemorial the professors of the healing art have been popularly reputed to be fond of obscuring their knowledge or want of it by a veil of verbal profundity. Witness the descriptions of physicians by Smollet, Fielding, *et al.* These fictitious practitioners invariably couched the simplest statement in a wealth of technical language calculated to make impressionable laymen reverent to their foundations. Even to-day some physicians are too much inclined to talk shop. Not ourselves to be sure, but some physicians. They are fond of referring to a contused orbit instead of a black eye, an acute gastralgia instead of a stomach-ache, and a fractured femur instead of a broken thigh. Even in medical circles we run across the specialist who constantly airs the abstruse jargon of his specialty; the psychiatrist, for instance, refers casually to confabulations, cyclothymia, metroeroticism, and regression of the libido as if we kept them in an instrument case, and the delvers in other specialties add their mites to the Babel. But other scientists are not free from this failing. In a paper in the *Journal of the Chemical Society* for September we find the word, tetradimethylaminotetraphenylhydrazine, a few lines farther on the writer speaks of trimethylindamino (dimethylaminophenylmethyl-ouquionedi-imide), and a little later on he refers casually to tetramethyldiaminotetramethyldiaminodiphenyldihydrophenazine. After these Gargantuan philological outrages let no one accuse the physician of expanding his ideas into polysyllabic labyrinths.

News of the Week.

Hospital Ship Torpedoed.—Official announcement has been made of the sinking of the Russian hospital ship *Portugal* with a large number of wounded on board in the Black Sea by a German submarine. It is said that the vessel displayed conspicuous Red Cross markings.

To Standardize Tuberculosis Treatment.—A bill designed to standardize the treatment of tuberculosis in the United States and to provide Federal aid in caring for indigent tuberculous persons, has recently been introduced into the House of Representatives. The bill authorizes the Secretary of the Treasury, within the appropriations made from time to time for such purposes, to aid State authorities in providing care and treatment for indigent tuberculous persons who are citizens of the United States but not legal residents of the State in which they are temporarily located, and for this purpose to designate such public and private hospitals as may be necessary. Such institutions are to be open to inspection by the officers of the Public Health Service, and are entitled to receive from the Federal Treasury a sum not to exceed seventy-five cents a day for each indigent person so admitted, provided that the State shall pay an equal amount to the institution. The bill has been indorsed by many members of the medical profession, as tending to advance the treatment of tuberculosis and prevent the migration of unfortunate persons suffering from the disease.

Fake Medical Degrees.—A scheme for the sale in Chicago of fake medical degrees was bared by the arrest, on the complaint of Dr. J. A. B. Adcock, secretary of the Missouri State Board of Health, of a candidate for license to practise in

Missouri. The candidate had presented a diploma supposedly issued by Marquette University School of Medicine, Milwaukee, Wis., bestowing on him the degree of M.D. On questioning, he admitted that he had received the diploma from men in Chicago who had represented that they were members of the University, and that he had paid them the sum of \$550.

Samuel D. Gross Prize.—The Philadelphia Academy of Surgery announces the Samuel D. Gross Prize of \$1,500, which is awarded every five years to the writer of the best original essay, not exceeding 150 printed pages, octavo, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens. Essays in competition for the next award will be received until Jan. 1, 1920, and should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 19 South 22d Street, Philadelphia." Each essay must be written in the English language by a single author, must be typewritten, and must be distinguished by a motto and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. The committee in charge reserves the right to make no award if the essays submitted are not considered worthy of the prize.

Personals.—Dr. James V. May, at present chairman of the New York State Hospital Commission, with an office at Albany, has been elected superintendent of the Grafton State Colony for the Insane at Worcester, Mass., succeeding Dr. H. Louis Stick, who recently resigned the position.

Dr. Harry Plotz of Mt. Sinai Hospital, New York, has received, according to newspaper dispatches, from the Bulgarian Government the award of a medal without swords, this distinction being the highest one which it is possible to confer on a Bulgarian army surgeon. The medal is bestowed in recognition of Dr. Plotz's services in aiding in the stamping out of typhus in Serbia and Bulgaria.

American Ambulance.—The first annual report of the committee in charge of the operation of the American Ambulance in Paris and its branches has recently been made public. The report covers the first year of its activities with a supplement covering the period up to February 1, 1916. At present, it is stated, the committee is maintaining hospitals with a capacity of more than 1500 beds, while its motor ambulances had, up to February 1, transported from the battle front to the hospitals more than 105,000 men. As a result of the fighting around Verdun since that date the total has been increased, it is estimated, to over 125,000. Beginning soon after the outbreak of the war with accommodations for 200 men in the American Ambulance outside of Paris, the service has grown until there are now accommodations for over 600 in the main hospital and in nearby hospitals available beds for 600 to 800 patients who are visited daily by the American surgeons. The hospital has the use of 165 motor ambulances in the field and in Paris, and a new section of 25 is soon to be added. All the drivers are chauffeurs, and most of them are American college men. They are often under fire, and 31 have received the "croix de guerre" for gallant conduct. The expenses of the American Ambulance amount to about \$500,000 yearly, all of which is met by contributions from

America. The work of the medical staff is entirely volunteer, and the hospital has been served by some of the most eminent American surgeons.

Street Accidents in March. The National Highways Protective Society has reported that during the month of March 22 persons were killed by automobiles in the streets of New York City, the total number of fatal accidents being 36; 9 of the victims were under seventeen years of age. During the first quarter of the present year, 85 persons were killed by vehicles on New York streets, 58 by automobiles, 16 by trolley cars, and 11 by wagons. In the corresponding period of last year 88 persons were killed.

Montefiore Home Expands.—Announcement is made in the annual report, just issued, of the Montefiore Home, New York, of the acceptance by the home of the offer from the College of Physicians and Surgeons and Bellevue Hospital to become affiliated with these institutions. The report states that during the year 1,569 patients were cared for at the home, all of whom, with the exception of 118, were free patients. At the close of the year there were 630 patients under treatment. The expenditures for the year were \$338,335, involving a deficit of \$3,751.

Infirmary to Change Name.—The trustees of the S. R. Smith Infirmary at Tompkinsville, N. Y., are planning to change the name of the institution to the Staten Island Hospital. The present name, it is said, is misleading, and increases the difficulty of securing nurses in the training school.

Women in Canneries.—There has recently been introduced into the New York State Legislature a bill amending the present labor law by granting to the Committee on Labor authority to permit women to work in the canneries for a limited number of days, for not more than twelve hours in any one day, and not earlier than 6 o'clock or later than midnight.

Gifts to Charities.—Mt. Sinai Hospital, New York, receives a bequest of \$5,000 by the will of the late Herman Nathan Walter of Harrison, N. Y.

Announcement has been made of the probable contest of the will of the late Mrs. Mary A. Haloran, which provides for the establishment of a cancer hospital as a branch of St. Vincent's Hospital, New York. The bequest set aside for this purpose amounted to \$260,000, and in addition the will contained bequests to other institutions amounting to \$30,000.

Civil Service Examinations.—The New York State Civil Service Commission will hold examinations on May 6, 1916, for the purpose of filling vacancies in the following positions:

Assistant physician, New York State Hospital for the Care of Crippled and Deformed Children, West Haverstraw, N. Y. Salary, \$1,200, increasing to \$1,500, with maintenance, etc. The examination is open only to men who are licensed medical practitioners in the State, and who since graduation have had at least one year's experience on the resident medical staff of a general hospital. Unmarried men are preferred.

Physiological chemist, State Department of Health, at a salary from \$1,800 to \$2,500. Applicants should have a thorough knowledge of the principles of organic and physiological chemistry, and must have had at least three years' practical experience in physiological or biological chemistry. The examination is open to both men and women.

Candidates for either position must be citizens of the United States and at least 21 years of age. Those desiring to take an examination should apply at once to the State Civil Service Commission, Albany, N. Y.

Health of New York.—The Department of Health reports that during the week ending March 25 the death rate in New York City was 15.16 per 1,000 of population, a drop of 1.54 as compared with the corresponding week of last year. The total number of deaths was 1,624 and 1,750 respectively, an actual decrease of 126 lives, and a proportionate decrease of 165. This saving resulted from the reduction of the number of deaths due to heart disease, influenza, bronchitis, lobar pneumonia, bronchopneumonia, pulmonary tuberculosis, and other forms of tuberculosis. There was, however, a slight increase in the number of deaths due to the acute contagious diseases and to nephritis. Despite the good health conditions prevailing during the past few weeks, the death rate for the first thirteen weeks of 1916 was 15.66 as compared with 15.12 for the same period of 1915.

Harvey Lecture.—The tenth lecture of the present series will be given at the New York Academy of Medicine on Saturday evening, April 8, at 8.30 P.M., by Prof. Stanley R. Benedict of Cornell University. Prof. Benedict's subject will be: "Uric Acid in Its Relations to Metabolism."

The Pilcher Semi-Centennial.—Dr. Lewis Stephen Pilcher of Brooklyn on March 28 completed 50 years of medical practice. The occasion was appropriately celebrated, and on the invitation of the faculty of the Long Island College Hospital Dr. Pilcher made an address in the Polhemus Clinic on "The Finer Characteristics of the Medical Life and the Influences That Make for Them."

Claims Discovery of Epilepsy Germ.—Dr. Charles A. L. Reed of Cincinnati in an address before the Medical Society of the Missouri Valley in St. Joseph on March 23 announced the discovery of a new microorganism, the *Bacillus epilepticus*, which he believes to be the etiological factor in epilepsy. Dr. Reed asserted that the new bacillus, like the tetanus bacillus, probably exists in the soil, and that it enters the body through the stomach and intestines.

Trouble in Medical Society.—At a regular meeting of the St. Louis Medical Society, St. Louis, Mo., on March 18, fifteen officials of the society handed in their resignations, and it was voted to reconsider the decision of the previous meeting freeing Dr. Bransford Lewis of the charge of unethical conduct. The resignations were tabled. Dr. Lewis was suspended by the Board of Censors of the society on the charge of having given to a St. Louis newspaper a copy of a paper he was to read at a meeting of the Mississippi Valley Medical Society in Louisville, Ky., before the paper was read, but at a meeting of the society to consider the charges he was reinstated. The resignations followed.

River Smoke Nuisance.—Because of the nuisance created during the summer of 1915 by the discharge of dense smoke from steam vessels in the territorial waters of New York City, the Department of Health held conferences with several of the owners of the vessels, sent letters of warning to the violators of the section of the Sanitary Code forbidding such discharge, and had the section published in the maritime papers. These

educational efforts, however, proved to be of no avail, and inspectors attached to the Sanitary Bureau were, therefore, sent out to serve summonses on some of the most flagrant offenders. Ten such cases brought before the Magistrates' courts and thence transferred to the Court of Special Sessions, have resulted in the imposition of fines in six instances and suspension of sentence in four. The inspectors have made trips on some of the steam vessels in the harbor and have given directions for the proper stoking of furnaces in which soft coal is burned, showing that it is possible to maintain suitable steam pressure without the discharge of dense smoke.

Memorial to Baccelli.—An appeal for funds for the erection of a statue of the late Professor Baccelli to be placed in the Policlinico at Rome, has been issued by Professor Rummo of Naples and Professor Maragliano of Genoa, vice-presidents of the Italian Society of Internal Medicine. Professor Baccelli was one of the founders of the Policlinico.

Obituary Notes.—Dr. JOHN W. DOHERTY of Jersey City, N. J., a graduate of the Castleton Medical College, Vt., in 1887, and a member of the American Academy of Medicine, the New York Medico-Legal Society, and the Hudson County Medical Society, died suddenly at his home, from heart disease, on March 26, aged 57 years.

Dr. SUZETTE E. DUNLEVY of New York, a graduate of the Homeopathic Medical College of Missouri, St. Louis, in 1879, died at her home on March 25, aged 81 years.

Dr. HARRY B. CASSELBERRY of Hazleton, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1886, died in Philadelphia on March 30, aged 53 years.

Dr. W. P. MILLER of Calhoun, Ky., a graduate of the Louisville Medical College in 1894, died suddenly at his home on March 17, aged 71 years.

Dr. ROBERT S. HART of Pisgah, Ky., a graduate of the College of Physicians and Surgeons, Baltimore, in 1869, and a member of the Kentucky State Medical Association and the Woodford County Medical Society, died at his home on March 21, aged 73 years.

Dr. MARY M. STRONG of Omaha, Neb., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1888, and a member of the American Medical Association, the Nebraska State Medical Association, and the Omaha-Douglas County Medical Society, died at her home on March 21, after a year's illness, aged 62 years.

Dr. WILLIAM P. BOLLES of Boston, Mass., a graduate of Harvard University, Medical School, in 1871, consulting surgeon at the Boston City Hospital, and a member of the American Medical Association, the Massachusetts Medical Society, and the Suffolk District Medical Society, died suddenly at Santa Barbara, Cal., on March 18, aged 71 years.

Dr. EZRA A. HOBBS of Framingham, Mass., a graduate of the Medical School of Maine, Portland, in 1869, and a member of the Massachusetts Medical Society and the District Medical Society, died at his home, after a week's illness, on March 25, aged 71 years. For thirty years Dr. Hobbs had been town physician of Framingham.

Dr. PERRY LEE BOLSINGER of Johnstown, Pa., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1900, died in the Hahnemann Hospital, Philadelphia, on March 21, aged 40 years.

Obituary.

CHARLES HENRY RICHARDSON, M.D.

NEW YORK.

Dr. CHARLES H. RICHARDSON, treasurer of the Medical Society of the County of New York, died at Roosevelt Hospital on Wednesday of this week, of heart disease, after an illness of several weeks. He was born in this city in 1861 and was graduated in medicine from the College of Physicians and Surgeons in 1884. He was a member of the New York State and County Medical Societies, of the American Medical Association, and of the New York Academy of Medicine. In 1904 he was elected treasurer of the County Society and held the office to the time of his death, being also a member of the Comitia Minor and a delegate to the State Society and to the American Medical Association.

NATHAN OPPENHEIM, M.D.

NEW YORK.

Dr. NATHAN OPPENHEIM died at the Hotel Belmont in this city on Wednesday of this week. He was born in Albany, October 17, 1865, and was graduated in arts from Harvard in 1888 and in medicine from the Medical Department of Columbia University in 1891. He was a member of the New York Academy of Medicine, the Medical Societies of the State and County of New York, the American Medical Association, the Metropolitan Medical Society, and the German Medical Society. Early in his medical life he specialized in the diseases of children and was the author of several books and numerous articles on the development, the hygiene, and the diseases of the growing child.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RETRENCHMENT COMMITTEE—ROYAL COMMISSION ON VENEREAL DISEASES REPORT—LONDON HOSPITAL MEETING.

LONDON, March 11, 1916.

THE retrenchment committee, as we call it, has presented its final report, dated February 21. This committee was appointed to inquire what savings can be effected in our public expenditure, considering the necessities created by the war, without detriment to the interests of the State. Questions of policy decided by parliament were not within the scope of this inquiry and expenditure on the army, navy or munition services was not to be considered by the committee. The first section of the report shows the enormous increase of the civil expenditure of recent years, amounting to nearly 200 per cent.—viz. from £32,000,000 in 1895 to £90,000,000. New grants and new administrative work are responsible for almost all this. As an example, of £40,000,000 increase in the civil service estimates, old age pensions take £13,500,000; national insurance and labor exchanges, £9,500,000; education, £12,000,000.

A number of measures for promoting economy are mentioned, some of which could not claim success on first trial, for in the year 1915-16 showed an increase of £205,000 in the estimates for the civil service and revenue. In 1916-17 there were both increases and decreases excluding the cost of new services required solely for war purposes. The re-

sult is an estimated net decrease of over £3,000,000 apart from a large reduction of capital expenditure effected by curtailing the issue of loans to local authorities. This reduction is expected to amount to £4,000,000 or more per annum. Other reductions are also contemplated and the report makes a number of recommendations for economies which concern factory inspection, reports of certifying surgeons, the Board of Control, the local Government Board; department, the Board of Education's medical work and national insurance. The committee holds that much might be done to reduce the expenses under the act, and to increase the sums available for benefit by simplifying its more elaborate provisions. Something has been done in this direction by departments, but more might be accomplished. Government departments requiring reports from local authorities should carefully revise their requirements without delay with a view to their simplification and extension after the war.

The report of the Royal Commission on Venereal Diseases was issued on the 2nd of this month. This commission was appointed on Nov. 1, 1913, to inquire into the prevalence of venereal diseases in the United Kingdom, "their effects on the health of the community, and the means by which those effects can be alleviated or prevented." It was laid down that no return to the policy or provisions of the Contagious Diseases Acts was to be within the scope of the inquiry. By this last committee eighty-five witnesses were called and to them were put 22,296 questions, from which it is obvious much information would be extracted of various degrees of importance, affording abundant material for criticism which will no doubt be extended to it from all directions. The committee which considered the acts of 1868-69 recommended their cautious extension. But since then such different proceedings and such controversy have filled our medical journals and occupied various associations that it is hardly practicable to do more at one time than take up a single point for discussion or for study.

At the London Hospital a meeting of governors was held on the 2nd inst., when it was reported that in the year past 18,933 inpatients were received, an increase of 600. The outpatients were rather fewer. In over 1900 cases anaesthetics were administered with two deaths. One hundred and twenty nurses were supplied to the army and twenty-six to the navy during the war. Ten of these nurses have been mentioned in dispatches in the last quarter. Three were killed in the accident to His Majesty's ship *Natal*. For the new nurses' home, named after Edith Cavell on the proposition of Queen Alexandra, £10,000 had been subscribed. Wards had been provided by the Grocers' Company for the salvarsan treatment, but are not yet open on account of the war, but they are now about to be opened and it is hoped will be fully worked.

3. Concerning the Raison d'Etre of the Term "Involution" as Applied to Melancholia.—J. W. Courtney refers to the common acceptance of ascribing to certain epochs in human life—puberty, climacteric, etc.,—with their organic upheavals as being cause for mental aberrations which may occur in the given epoch and to attach to these aberrations names suggested by the epochs. He takes issue with this procedure and endeavors to show that there is no pathological, differential, or descriptive reason for such conclusions. He takes involutional melancholia as an example and cites his views on Kraepelin's statement that this condition stands in direct causal relationship to *general* involutional changes, and that it embraces all pathological anxiety-depressions of the last half of life, which do not represent episodes in other forms of mental disease. It occurs between forty and sixty-five years of age, and is 60 per cent. among women as against 50 per cent. among men. Kraepelin considers that heredity plays but a small part as compared with acquired disposition, and that the condition is a dynamic one. Courtney refutes these statements because to him it is inconceivable that, in the absence of all other causes, the state of organic involution which normally obtains at forty is capable of producing a mental disorder in nowise distinguishable clinically from that produced by the same agent at the age of sixty-five. He furnishes more than one insuperable argument against the climacteric as a causal factor of this condition in women. First, that the number of female melancholics exceeds that of the male by only 10 per cent.; second, that melancholia sometimes makes its appearance either several years before or many years after climacteric changes being to manifest themselves; and third, that both pregnancy and lactation are not infrequently accompanied by a complex of morbid mental symptoms in no essential respects different from involutional melancholia. Also that many cases of irrecoverable involutional melancholia terminate in a mental state indistinguishable from that considered the product of disordered evolution and which is called dementia precox. If any heed is given at all to the law of cause and effect it must be admitted that identity of effect signifies identity of cause, and this single fact should restrain all attempts at sharp differentiations in clinical psychiatry. Are involutional processes responsible for the intensification of morbid feelings which transforms psychasthenia into melancholia? That the answer must be in the negative is determined by two facts: First, the march of events in certain cases in adolescents where the symptom-complex is at the outset that of psychasthenia and the terminal stage a dementia, called precox, which has no demonstrable connection with general involutional processes, yet is indistinguishable from one terminal stage of the disease designated, under present usage as involutional melancholia; the second is drawn from the observation of depressed states identical with so-called involutional melancholia, which make their appearance during the floodtide of mental and physical vigor, run their course and recover, and which may even recur several times before involution processes in the economy have fairly started.

7. An Analysis of Fourteen Cases of Diabetes Mellitus Unsuccessfully Treated by Fasting.—Joslin, Brigham, and Horner, while thoroughly believing in the fasting treatment of diabetes, have had under their care the fourteen cases of this condition which did not

respond to their treatment, and of which they give a detailed account of the reasons for the apparent failure and deaths. The number of cases fasted from May, 1914, to December 1, 1915, has been 125; of these, fourteen patients have died. They say that in the light of later experience eight of these deaths might have been avoided or deferred, but no treatment could have saved the patient with cancer. Seven of these cases died because the fasting treatment was not completely carried out. Of the remaining seven cases, death in two was associated with an accompanying infection; one case represented extremely severe diabetes of long duration; in another cardio-renal complications and goitre were present; in a fifth cancer of the bladder; and the sixth syphilis. The cause of death of the remaining patient probably had nothing whatever to do with diabetes. A detailed account is given also as to the reasons why the fasting treatment was not thoroughly carried out in the seven cases, and of the treatment of the other seven cases. They consider that changes in the diet and régime of patients who have suffered from diabetes for many years are always dangerous, and particularly so with the case of extraordinary length. Treatment of such individuals should never be undertaken lightly nor without a full realization of the danger involved. They summarize their treatment as follows: Fasting until sugar-free. Carbohydrate tolerance, which is begun when the twenty-four hour urine is sugar-free. Protein tolerance, which is begun when the urine has been sugar-free for two days. Fat tolerance, is commenced while testing the protein tolerance. Reappearance of sugar, which demands fasting for twenty-four hours or until sugar-free. Weekly fasting days. Whenever the tolerance is less than twenty grams carbohydrate, fasting should be practised one day in seven.

4. Guelpa's Discovery.—J. H. Kellogg in discussing the importance of fasting in the treatment of diabetes says that in July, 1910, Guelpa, of Paris, presented a paper entitled Starvation and Purgation in the Relief of Disease, before the British Medical Association in London. Maintaining that diabetes is due to intestinal toxemia, he cited clinical results which demonstrated that by abstinence from food and through evacuation of the intestines by a saline laxative sugar may be made to disappear from the urine in most cases of diabetes within three days. If the sugar returned on the resumption of feeding, a repetition of the fasting and purgation once or twice caused a complete and often permanent disappearance of sugar. Little attention was paid to the observations of Guelpa by English-speaking physicians, although the French medical societies recognized at once the value of his work. Kellogg states that the discovery which entitles Guelpa to much credit is the fact that a diabetic may abstain from food for several days without inducing acidosis or diabetic coma, since in health it was known that

a fasting man develops acidosis within a few hours. Guelpa also laid special stress upon the importance of reducing weight, to which his attention had been called by the experiments of another Frenchman. Other advantages secured by the fasting method are: 1. A very marked change in the intestinal flora with a reduction of the number of bacteria. 2. Lowering of blood pressure when high, with increase in the percentage of hemoglobin and the number of red cells. 3. Reduction in the volume of the viscera when enlarged, especially of the liver. 4. The disappearance of pains in the joints and muscles. 5. A general feeling of well being, suppleness, and readiness for mental or physical activity and less necessity for sleep. Kellogg and his colleagues have verified these results in the treatment of 267 cases within the last two years. Careful investigation discloses the remarkable fact that when a diabetic is deprived entirely of food, he suffers a smaller loss of tissue than when taking the ordinary diabetic diet of meat and fats. The results are especially brilliant in young subjects who heretofore almost wholly baffled therapeutic effort. Allen, at the Rockefeller Institute, has for several years obtained remarkable results along the same line of treatment as Guelpa. Guelpa's treatment, aside from causing quick disappearance of sugar from the urine, lessens the danger of diabetic coma, gangrene, arteriosclerosis, renal disease, and other grave toxic complications of diabetes.

5. **Migraine.**—Antonio H. Molina-de Saint Remy in giving the cause, treatment, and cure of migraine defines it as an affection of purely nasal origin, though manifested by pain in the ophthalmic branches of the fifth nerve, and even in the occipital region. The disease usually comes on at puberty and lasts intermittently until sixty years of age. The symptoms are too well known to need description. The attacks begin as a rule in the morning on rising, get rapidly worse, and reach their acme several hours, or in some cases, several days later. The sufferer then is relieved and between attacks feels unusually well. Migraine is often confounded with headache caused by ocular trouble, which becomes worse after the eyes have been used and is relieved when they have been rested. Not so the headache of migraine. It runs its course, is present on rising, gets worse, especially on lying down or lowering the head, independently of whether the eyes are used or not. Pressure upon the sphenopalatine ganglion, caused by swelling of the mucosa of the middle turbinate impinging against a relatively high deviation of the nasal septum, by disturbance of the local circulation, ends in a reflex spasm of the cerebral vessels, which accounts for the vomiting, nausea, oppression, etc. It becomes clear why the disease comes on at puberty, for then the nasal septum begins to bend from pressure upon it by the faulty development of the facial bones; the disproportionate growth of the frontal and maxillary causes the vomer to yield. Double migraine is produced because the septum may be so thickened as to obstruct both nostrils and compress both ganglia or plug the nostril posteriorly, resulting in *occipital* (Dana) migraine. Here also is made clear why spontaneous cessation of the disease occurs late in life, when the nasal mucosa is no longer erectile. There is no migraine if the septum be normal. The intermittency of the attacks so characteristic of the disease can be explained only by the erectility of the mucous membrane of the "swell bodies," which by their susceptibility, react to stimulation by atmospheric conditions and barometric changes. Once the cause is known, treatment is indicated, namely, the thorough and complete submucous resection of the nasal

septum. It is of utmost importance to bear in mind the true pathology, because if the resection be not properly done some points of contact may be allowed to remain and so render ineffective the operative interference. Treatment of the turbinates does no more than to relieve slightly the condition. Thorough extirpation of all the bony defect of the septum, with due care to avoid perforation, which is of importance in these cases, will give complete and prompt relief. No amount of swelling of the middle or superior turbinate can then cause pressure, as there remains only the resilient membranous partition after the resection, which yields to their increase in volume.

1. **Inhibitory Properties of Magnesium Sulphate and Their Therapeutic Application in Tetanus.**—S. J. Meltzer states that it is not improbable that there are many who know that this salt is being used in the treatment of tetanus, but it is possible that many are unfamiliar with its pharmacological action on which this method of treatment is based. It is conceivable that it is assumed by some that any favorable therapeutic effect Epsom salt may exert on this condition rests on its well known action as a purgative. He goes into detail of the phenomena of inhibition in biology in order to arrive at the theoretical character of the inhibition property of magnesium salts in relation to tetanus. By an analysis of numerous living phenomena he came to the conclusion that all living functions are continually controlled by two opposing forces: augmentation or action on the one hand, and inhibition on the other hand. The state of every function at every moment depends on the relation and the predominance of each of these opposing functions. After long experience he states that the dominant action of magnesium salts on the living body, no matter by which way it is administered, consists in depression or inhibition. His theory assumes that the magnesium solution contained in the lymph bathing the synaptic membrane enters with ease into these spaces, and interrupts the passage of nervous afferent impulses from one neuron to the other, especially of such impulses for which there is a less readily prepared path for transmission than the paths existing for normal active reflexes. It should be borne in mind that this magnesium treatment in no way precludes a simultaneous treatment with antitetanic serum. Even if the magnesium sulphate would do no more than relieve the most severe symptoms, the convulsions and the tetanus, it would be a duty to use it. Meltzer summarizes his general plan of treatment as follows: In every case of tetanus, 1.2 c.c. of a 25 per cent. solution of magnesium sulphate should be given by subcutaneous

injection three or four times a day throughout the entire disease. When the disease is complicated by severe tetanic attacks, 1 c.c. of a 25 per cent. solution for every 10 kg. (20 pounds) body weight (in adults) should be given by the intraspinal method. When the disease is attended by immediately dangerous tetanic complications, from 2 to 3 c.c. per minute of a 6 per cent. solution of magnesium salts should be given then by an intravenous injection until dangerous symptoms subside or the respiration becomes shallow or too slow. When the respiration seems to become impaired in consequence of the administration of magnesium salt by the intravenous, intramuscular or subcutaneous methods, calcium chlorid should be injected in the manner described above. It is advisable to have at hand an apparatus of intrapharyngeal insufflation ready for use, whenever the respiration becomes slow or shallow. Finally, the simultaneous treatment by anti-tetanic serum should not be neglected.

2. **The Systolic Blood Pressure in Pregnancy.**—Fredrick C. Irving gives the result of his observations on five thousand consecutive cases in the pregnancy clinic of the Boston Lying-In Hospital, which cover from February 28, 1912, to March 11, 1915. At her first visit, each applicant is given a thorough examination, physical and obstetrical, the urine is examined, and the systolic blood pressure is determined. As a result of this work Irving deducts the following conclusions: 1. In 80 per cent. of pregnant women, the blood pressure ranges from 100 to 130. 2. In 9 per cent. the blood pressure may be below 100 once or more. A blood pressure below 90 does not mean that the patient will have shock unaccompanied by hemorrhage at the time of confinement. 3. In 11 per cent. of cases, the blood pressure may be above 130 once or more. Age, nationality and parity seem to have some influence on blood pressure. High blood pressure in the young is more frequently a sign of toxemia than in those over 30. 4. Elevated blood pressure is more commonly an index of toxemia than is albuminuria, and it is apt to be an earlier sign. The degree of elevation points more surely to the likelihood of toxemia than does the degree of albuminuria. Both, however, are of the utmost importance. 5. Isolated cases of elevated blood pressure unaccompanied by albuminuria or evidences of toxemia occurred not infrequently. Usually they responded to free catharsis. Some pressures remained elevated in spite of treatment, and apparently were normal, during pregnancy at least, for the patients who exhibited them. 6. A progressively rising blood pressure, often from a low level, even though it never reaches the arbitrary danger point, should be regarded with apprehension as a most valuable sign of approaching toxemia. 7. Toxemia is much more common with a blood pressure above 150 than it is below that point. 8. Most cases of eclampsia occurred with a pressure of 160 or more. Eclampsia may, however, occur with a pressure of only moderate elevation. 9. All toxemics developed both albuminuria and elevated blood pressure. 10. It is significant that two thirds of the patients who developed convulsions absolutely neglected advice and refused to return to the clinic. Had these patients been discharged against advice during pregnancy for disobeying instructions, very favorable statistics would have been obtained. The hospital feels that it would be most unjust to the ignorant foreigners who constitute the vast majority of its patients to desert them when they most needed skilled hospital care. With proper cooperation from the patients, and eliminating the fulminating cases which develop in a few hours, there is no doubt that eclampsia should be practically a preventable disease.

6. **The Use of Kaolin to Remove Diphtheria from the Nose and Throat.**—B. Rappaport states that since his last report of this method, he has made a study of one hundred unselected cases, ninety-six being diphtheria patients and four pure diphtheria carriers. A pure diphtheria carrier is a person with diphtheria bacilli in the nose or throat, who yields no history of sore throat or other symptoms of diphtheria, and who gives a negative Schick test. Kaolin is applied as follows: Crude kaolin, which is moist and lumpy, has not the adsorptive power of the thoroughly dried and finely powdered product, so it is dried for several days in a bacteriological incubator, then powdered through a fine flour sieve. Each morning the small amount necessary for the day's treatment is taken to the patient's room—on damp days it is taken from the incubator oftener, two or three times during the day. Kaolin must be perfectly dry and finely powdered or the results will be disappointing. Whenever possible, the application should be started as soon as the acute symptoms have subsided, and the kaolin must be distributed thoroughly over the diseased surfaces. In small children—of less than three years of age—it is best applied directly to the nasal mucous membrane, by means of a rubber bulb attached to a glass tube with a tapering end that fits the nostril. Six treatments at two-hour intervals during the day is the practice. It is necessary at each treatment to remove the old kaolin, as it prevents the fresh kaolin from reaching the mucous membrane, and for this purpose an alkaline spray does well, such as for a solution of sodium bicarbonate and sodium borate, two per cent. each. In the case of older persons, the powder is best applied to the pharynx by having the patient swallow it. Four half-teaspoonful doses at two hour intervals, six times during the day, are given as a rule. Before dismissal of any patient, the cultures from nose and throat must be negative for at least three consecutive days after the discontinuation of the kaolin treatment, which is continued from two to five days after the first diphtheria-free culture. The average stay in the hospital of each patient was 7.84 days less than that for the untreated patients—a shortening of 23.4 per cent. Kaolin is not bactericidal, but when properly applied by its adsorptive power mechanically removes bacteria with which it comes in contact, and its application to the nose and throat helps to remove diphtheria bacilli and to shorten the period of quarantine. This action of kaolin is interfered with by various local pathological conditions, which must be remedied as promptly as possible. Removal of tonsils and adenoids is indicated when diphtheria bacilli persist unduly in spite of kaolin.

9. **Foot-and-Mouth Disease in Man.**—Sutton and O'Donnell describe this disease as among the acute exanthemas, although the eruption is seldom of generalized distribution. One attack confers only limited immunity, as short as ten or twelve days, hence the disease is an extremely infectious one. It has been recognized in continental Europe for more than two centuries, but in this country it has attracted attention only within the past two decades. The eruption is vesicular in character and involves the mucous membranes as well as the skin. In cloven-footed animals, the mouth and the interdigital spaces are the regions commonly involved. The disease is more prevalent in summer than in winter. The microorganism causing this condition has not yet been isolated. The lymph contained in the vesicles is very virulent, and infection may result through the medium of contaminated clothing or food. Stock markets play an important part in the transmission of the malady according to Hutyrá and Marek. Cattle are the most susceptible, then hogs,

sheep, and goats. Horses, dogs, and cats, and rarely chickens, pigeons, and other fowl are affected. In man it is usually acquired through the ingestion of contaminated milk or milk products. Direct inoculation is of infrequent occurrence, and the disease is of low virulence (Bertarelli), but children are more severely affected than adults. The period of inoculation is from two days to two weeks. Moderate constitutional symptoms occur, with fever, general malaise, and in children, gastrointestinal symptoms. The mouth becomes dry, the mucous membrane swollen, reddened and glazed. The palpebral conjunctiva and genital mucosa may be involved. In three or four days vesicles appear on the dorsal surface of the hands and feet, and sometimes on the nose, face, ears, and knees. The base of the lesions is purplish and ill defined, and the distribution is roughly symmetrical. The clear lymph in the vesicles becomes pyogenic in character, and in a few days the pustules dry up leaving no scar.

10. Radium in the Treatment of Lymphangioma Circumscriptum.—Frank E. Simpson presents a report of a case of lymphangioma circumscriptum treated by radium. The case was that of a woman aged twenty-one, who came under Simpson's care at the Cook County Hospital, Chicago, in April, 1914. The tumor was situated over the right buttock and the inner surface of the right thigh, covering an irregular surface of approximately eight by fifteen centimeters involving the skin of this area. It had been present since the patient's earliest recollection and was seen to be composed of innumerable thick-walled vesicles on which had developed in places a thickened hyperkeratotic epithelium giving a wartlike appearance, parts of the tumor were more flat and were bluish black, being evidently made up of blood vessels. That the tumor would yield to radium was expected from the success already obtained in the treatment of pure angiomas of the skin and from Simpson's observations of the general effects of this agent on the skin and other tissues. The treatment was as follows: The most prominent part of the tumor was attacked first. Radium-varnish applicators of one-quarter strength were usually employed. Four applicators of this type covering an area of 16 sq. cm. were applied unscreened for one hour a day on four successive days. A series of four similar courses about four to six weeks apart sufficed to level the surface of the most prominent portions of the growth. As the height of the tumor decreased the treatments were of an hourly seance each day (0.1 mm. lead screens being applied over the surface of the applicators) for five successive days. Two series of treatments of this sort at intervals of six weeks sufficed to cause complete retrogression of the growth. In the less infiltrated parts a linen "toile" (one-twentieth strength) was sometimes used. With this applicator screened with 1/100 aluminum a series of applications of an hour each day on five successive days, repeated four times, at intervals of about six weeks, sufficed for decolorizing and removing these areas. The use of radium in these rare cases would seem to be the method of election.

4. Diet as a Factor in the Causation of Mental Disease.—Charles Mercier reported thirty-five cases of mental conditions caused by errors in diet in the March 4 issue and in this number states that it is just forty years since he first ventured to call in question the accepted doctrines of the causation of nervous diseases. Among others he takes issue with Freud, and considers that his theories may be supplemented by researches less recondite. Granted that one or more errors in diet were found among the antecedents of mental disease, how would it be possible to assure oneself that errors were actual causes, and not mere causal associates or antecedents of the disease? He has recorded a number of cases of persons who have sought relief from mental disease; out of the thirty-five cases so reported only one could be certified as insane. He insists upon this especial fact because of the universally accepted doctrine that disorder of mind is equivalent to insanity, that they are the same thing. He has combatted this theory and considered that many and varied mental disorders are compatible with complete sanity. The peculiarities in diet which preceded and accompanied the mental disorder in his cases were mainly of two kinds—deficiency of meat, or excess of fat, starch, or sugar. The deficiency in balance of diet for the particular individual is practically the basis of his cause. In the cases suffering from excess of fat in the diet, headache proved to be one of the prominent symptoms; and Mercier suggests that this is not the only cause of the headache, but merely that deficiency of meat alone is not a cause of headache. It seems that it is a cause of confusion of mind, however, as the cases lacking sufficient meat diet, but taking excessive starch or fat diet all complained of dazed, confused mental states. Depression, defects of memory, and screaming fits may accompany the dazed state. Another point Mercier brings out is that those symptoms that seem to be due to excess of fat, starch, and sugar in the diet, and are relieved by diminishing these constituents, are almost always worse in the morning, clear up towards afternoon, and are often absent in the evening. Mercier states that he does not hold that there is only one cause of mental disease, but that by applying the true principles of ascertaining causation, in a small number of cases in proportion to the whole, but considerable in the aggregate, the disease is due to error in diet and can be cured by rectifying the error in the balance of diet.

6. A Search for Typhoid Carriers Among 800 Convalescents.—Stokes and Clarke carried on this investigation late in 1914 and early in 1915, when a serious epidemic of typhoid had occurred among the civilian inhabitants of an area about to be taken over by British troops. The patients were searched for in their homes by the R. A. M. C. authorities and removed to hospital. Very few of the first series of patients arrived in the acute stage. Difficulties were increased as many of the patients had been inoculated with stock army vaccine, many others had been treated with mixed typhoid group vaccines while ill, and very few knew if they had or had not been inoculated. Of 927 admissions it was estimated that 117 had not had typhoid, but had suffered from tuberculosis, diphtheria, or bad food. A bacteriological diagnosis was definitely obtained in only 165 cases, the infecting organism being isolated from the blood, excreta, rose spots (10 cases), and from the gallbladder of some that came to necropsy. The proportion of seven cases of typhoid infection to one paratyphoid B. is possible for the earlier part of the epidemic, but cases admitted during the later stages showed four typhoid to five paratyphoid B. In the remaining cases the diagnosis depended on the

agglutination test. The patients were examined at varying periods of convalescence, in the early part of the investigation at the tenth to sixteenth week after commencement of the illness, later whenever the medical officer in charge regarded them as fit for discharge. An arbitrary period of three months after the first onset of the fever is taken as the time when a patient should have ceased to excrete typhoid bacilli. Up to that time patients excreting the bacilli and not after are regarded as temporary carriers; if they continue to excrete they are considered as chronic carriers. Their percentages show that females more often become chronic carriers than males, the incidence of such being three to one. Two examinations were done on successive days until they should have ceased to excrete typhoid bacilli. Six consecutive negative examinations were required as the standard before the patient was deemed fit for discharge. Two methods of treatment were tried. Arsenic, as salvarsan, was injected into two intestinal carriers but did not alter their condition, and thirty-three temporary carriers were given urotropin for about ten days, and after an interval of a week proved on examination to give four consecutive negative results. Hence urotropin proved the more valuable means of treatment.

4. Work at a Base Hospital. W. Rankin.
5. Ulcero-membranous Stomatitis and Gingivitis Among Troops on Active Service. F. B. Bowman.

2. **The Principles of Treatment and Their Application to Wounds.**—Charles F. M. Saint describes a wound as the local effect of an irritant—noninfective or infective—on the tissues. His principles of treatment offered are: (1) remove the cause; (2) combat the effects; (3) assist the reaction; (4) prevent complications, or deal with them if they have arisen. (1). A sterile metallic body gives rise to a minimum of irritation sufficient for the production of a fibrous capsule, whereby the body is completely isolated, and in a large proportion of these cases missiles have come to be regarded as sterile, particularly rifle bullets presenting a small wound of entry. When the bullet presses on or produces irritation of nerves, interferes with the movements of a joint, etc., it must be removed, but operative measures for the removal of metallic bodies ought to be restricted where x-rays are not available. The commonest and most important indication for the removal of bullets, etc., is sepsis in the track; and in operating, it must be remembered that too small an incision increases shock from the excessive retraction demanded, and the longer time necessary for the operation. During this campaign it has been found that the degree of shock is greater than the nature of the injury would seem to warrant, due to excessive mental and nervous strain, rough transportation, etc. The requirements of the milder cases are met by a good meal, with some tea or cocoa, immediately followed by quiet and sleep. In the more severe cases, rest, with the foot of the stretcher elevated, is essential. Pain and restlessness demand morphine, one-half grain hypodermically. Stimulants by mouth must be given with caution, as they tend to increase shock. Subnormal temperature is met by the application of heat externally and internally. Transfusion, usually saline, may be given by rectum, subcutaneously, or intravenously; intermittent administration of saline per rectum being

the most common method as sepsis is eliminated. Six to ten ounces of saline, with half an ounce of brandy may be administered in this way every three or four hours. Rectal injection of one pint of hot coffee and half an ounce of sugar is an excellent substitute. In local conditions, wounded blood vessels must be treated to stop hemorrhage, shock, and sepsis. First-aid work may be utilized, and the importance of ascertaining that no tourniquet is left on a limb too long, anything above two hours being dangerous. Removal of the irritant, if noninfective, may be accomplished (1) by forceps, or other instruments, (2) by irrigation, and (3) by the introduction of hydrogen peroxide. These are done after due consideration in the absence of the x-ray. Infective irritants are met by the means above, and if not effective, pure carbolic acid or hypochlorous acid is used. In this type of wounds free excision is often demanded. When pure carbolic acid is used over an extensive area it is to be followed by alcohol in the wound. Increased metabolism is gained by the recumbent position of the patient, easily assimilated liquid nourishment, fresh air, plenty of fluid, and baths. Abscesses must be evacuated and free drainage allowed. Carbolic acid is used freely in head wounds even when the brain is exposed, always keeping in mind the use of alcohol following the carbolic acid in the extensive wounds.

5. **Ulcero-membranous Stomatitis and Gingivitis among the Troops on Active Service.**—F. B. Bowman gives the results of his study of a hundred cases of the above named condition found among the Canadian troops returned from the front. Ulcero-membranous stomatitis resembles symptomatically Vincent's Angina, and may be superimposed upon a syphilitic infection of the mouth and throat. Upon the gums, tongue, mucous membrane of the cheeks, and tonsils, ulcers are to be found, that are covered with a white, friable membrane easily removed, leaving a bleeding surface beneath. In advanced cases the condition strongly suggests scurvy. Foul breath, bad taste, submaxillary and sublingual glandular enlargement occur, and the temperature ranges around 102 F. Accompanying this constitutional disturbance is lassitude and lack of "go," together with severe depression. This disease may become so severe as to present symptoms of noma. It is extremely contagious, as shown by the quick infection among the troops. The germs found by smears are Vincent's spirochete, and *B. fusiformis*. Tunnicliff has found that she was able to obtain distinct transition from the bacillary to the spirochetel form of Vincent's organism, and it is easily distinguishable from *Spirocheta dentium* and the *Treponema pallidum*. Bowman found after trying emetine and also salvarsan, that another form of arsenic could be used which cured this condition. Emetine had no curative effect and salvarsan was too expensive for the soldiers. The following formula gave remarkably rapid and favorable results: Vini ipecacuanhæ ʒ ss, glycerini 5 j, liquoris arsenicalis ad ʒ j; M., fiat mist. Sig.: To be used as a mouth wash; do not swallow. Label "Poison." Where the gums only are affected the solution may be applied by means of an applicator, after cleansing the pus from the pockets around the teeth. Ulcers on the cheeks or tonsils should be touched twice a day with the solution. All patients, whether or not the gums be infected, are instructed to drop ten or fifteen drops on to a toothbrush twice a day and to brush the teeth and gums vigorously.

War Literature of Internal Medicine.—Reckzeh concludes his review of this literature. He mentions the

supposed discovery of the etiology of typhus by the American, Proescher, without criticism. Jürgens has practically proven the doctrine that typhus is spread by body lice, had any further proof been needed. The peculiar, even unique method of spreading and the successful prophylaxis are the chief documents here. Lindner states that there can be a typhus without louse propagation, but this is not infectious. The louse not only transmits the infection but activates it. According to Wiener an early symptom of the disease and one which persists throughout, is conjunctival infection. Fraenkel's important histological discoveries in connection with the exanthem have been repeatedly corroborated and their diagnostic value is admitted. Typhus and typhoid can imitate each other clinically. Boral has shown that lice cannot transmit typhus during the incubation period. Lipschutz in a special epidemic saw hemorrhage occur at the site of preexisting acne lesions. Not much has been added to our knowledge of treatment. Authors differ as to the value of urotropin. Cresol in powder form has shown itself the best antilouse remedy. Beds have been made with louse traps—deep grooves filled with cresol solutions—which are sure death to the lice which must traverse them to reach the patient. For protecting the physician and personnel of the hospital suits made of glazed material, such as oil-cloth, serve best, for the lice cannot maintain a foothold on them.

Pestilences of the World War.—Möllers refers first to the march of Napoleon's half million seasoned troops upon Moscow. No one could have imagined that such an army would soon become extinct. But one battle was fought on the way. One fifth of the troops perished from infectious diseases, principally typhus. During the Crimean war the Russians lost 600,000 troops from disease. Great percentage losses of this sort persisted until Koch's advent and compulsory vaccination had alike contributed to suppress several of the worst plagues. With typhoid remaining as the worst of the endemic, ways were devised to prevent it, at first through warfare against insects and unsanitary water and eventually through immunisation. Measures of the same character dealt successfully with the occasional menace of cholera. Dysentery, once a fearful menace, appears to have been overcome chiefly by general advances in sanitation and personal hygiene and by prompt treatment of diarrheal cases. There remains typhus, so greatly dreaded in warfare, which has been kept checked in Germany while still claiming a high toll in Russia. Many Russian lives must have been saved in the German prison camps, not as much from humanitarian reasons as for the protection of Germany. Serbia has also suffered heavily from typhus. Typhoid still remains the most feared disease because privations and hardships so weaken the individual resistance that immunisation efforts often fail. In the army of the United States the stamping out of the disease was carried out on intact subjects whose youth, despite the vigorous constitutions, invites the disease. It has not been realized that greatly weakened constitutions may also invite the disease irrespective of age provided the victim has been an unconscious host for the bacillus.

Yeast as Food.—Schrumpf refers to the nutritive yeast prepared at the Berlin Institute for Fermentation Industries and Starch Fabrication. It contains 54 per cent. albumin and 3 per cent. fat. According to the makers its taste is agreeable and it can be used in the preparation of many kinds of food. Although

of vegetable origin it strongly resembles meat in several respects, such as albumin content, taste and stimulating properties. To replace meat entirely in an ordinary day's ration some 120 gms. would probably be required. This amount would be far less bulky and much cheaper than meat so that economy of diet is promoted in a twofold manner. About 80 gms. yeast will replace 200 gms. meat. This 80 gms. are not to be taken in the pure state, for 30 gms. can be incorporated into bread and 20 gms. more cooked up with vegetables (potatoes, tomatoes, celery). Unfortunately the yeast bread has an unpleasant taste and slices must have a "spread" either of butter or jam or both. Some young recruits who were fed some yeast soup could not finish their portions. Convicts were made to ingest yeast in some form in relatively large amounts, over considerable periods, and some lost weight, although other gained or held their own. It will be recalled that in giving yeast, whether wet or dried, to the victims of furunculosis, many patients are unable to take the treatment, so repellant is the yeast taste. No one has succeeded in overcoming the smell or taste of the latter and until this is done manufacturers' claims of its nutritive value will avail nothing.

Treatment of Digestive Diseases in the American Lazaretto at Munich.—Jung mentions some of the catchwords used in dieting. Thus diarrhea cases were allowed only scalded flour porridge and acorn coffee. In colitis, achylia, and cirrhosis of the liver only pultaceous food is given; in gastritis nothing but broths and soups. In hyperacidity a mixed, bland diet, with no opportunity for mechanical or chemical irritation. In ulcer, milk and mild soups and tapioca. In nephritis, milk for a time, followed by pultaceous foods, meat free. In more detail the author describes his normal and pultaceous diets, administered to two sets of patients in different dining rooms. In the normal room patients ate the typical German diet and were allowed beer or milk to drink, with a cigar after the meal. This regimen was naturally intended for those able to profit by it. In the "pap" room were gathered those shot through the mouth as well as those with gastroenteric disorders. Everything that was not fibrous in texture was passed through a coarse sieve while meats and the like were forced through a machine. The success of such finely communicated food, irrespective of quality, in the treatment of a number of digestive affections recalls the corresponding results of Fletcherism, to the effect that with complete mastication many substances become digestible which would give trouble if imperfectly chewed. Analysis of stomach contents revealed a high percentage of subacidity and achylia and the corresponding low rates of hyperacidity. There was little use for the alkaline tablets which had been provided in large amounts. Professor Adolf Schmidt had previously called attention to war achylia and it certainly seems that a marked difference exists between peace and war digestion. The Bavarian is naturally a meat eater, and often leaves his spinach, etc., quite untasted. It seems that in peace times his beer serves to balance his diet. When the war began he did not at first do well on the balanced army rations.

Digestibility of Proteins in Milk.—Holt says we have seen thus far that digestion of the protein of cow's milk is a much easier matter than was formerly supposed; that injury may occur in high protein feeding, but usually only when amounts much in excess of those commonly used in infant feeding are given; neither laboratory nor clinical evidences show that protein is harmful; and that the deficiency of cow's milk casein in certain amino-acids may be made up by giving an excess of this protein.—*Archives of Pediatrics.*

Book Reviews.

DISEASES OF NUTRITION AND INFANT FEEDING. By JOHN LOVETT MORSE, A.M., M.D., Professor of Pediatrics, Harvard Medical School; Visiting Physician at the Children's Hospital; Consulting Physician at the Infants' Hospital and the Floating Hospital, Boston; and FRITZ B. TALBOT, A.B., M.D., Instructor in Pediatrics, Harvard Medical School; Chief of Children's Medical Department, Massachusetts General Hospital; Physician to Children, Charitable Eye and Ear Infirmary; Consulting Physician at the Lying-In Hospital, Boston; Collaborator to the Nutrition Laboratory of the Carnegie Institute of Washington. Price, \$2.50. New York: The Macmillan Company, 1915.

THIS book is a notable addition to the many volumes on infant feeding that have appeared during the past few years. Its chief merit lies in the thorough manner in which it presents the experimental and clinical data upon which is based a rational system of infant feeding. The method described is the one originally evolved in Boston and now taught to the students in the Harvard medical school, namely, the percentage method. In describing the home modification of milk the authors emphasize the fact that it makes no difference whether gravity cream, 10 per cent. cream, top milks, skimmed milk, or whole milk is used, provided the method is understood and used correctly. The authors have found a satisfactory method in the use of gravity cream and skimmed milk. Among the most valuable chapters in this book are those which deal with the physiology of digestion, the digestion and metabolism of fat, carbohydrates, and protein; the metabolism of the mineral salts; the energy metabolism of infants; the bacteriology of the gastrointestinal canal, and the stools in infancy. The subject of breast feeding is dealt with in satisfying detail. In the section on artificial feeding there are separate chapters on the chemistry and biology of cow's milk; its bacteriology and chemical tests; sterilization, boiling and pasteurization; certified milk; general principles of artificial feeding; the prescribing of modified milk, and the feeding of premature infants. The section on diseases of the gastrointestinal canal includes the following topics: spasm of the pylorus, hypertrophic stenosis of the pylorus, nervous disturbances of the digestive tract, disturbances of digestion, indigestion with fermentation, infectious diarrhea, and constipation. The section on diseases of nutrition comprises chapters on rickets and infantile scurvy. This book may be recommended to the student and general practitioner as a scholarly exposition of the subject of infant feeding.

ORAL SURGERY: A Treatise on the Diseases, Injuries and Malformations of the Mouth and Associated Parts. By TRUMAN W. BROPHY, M.D., D.D.S., LL.D., Sc.D., F.A.C.S., President and Professor of Oral Surgery, Chicago College of Dental Surgery; President International Dental Federation; Member American Medical Association, Illinois Medical Society, Chicago Medical and Dental Societies, Illinois State Dental Society, National Dental Association; Honorary Member of all National Dental Associations of Continental Europe, North America, and Several Other Countries; Medalist Odontological Societies of Paris and Italy, and of New York State Dental Society; Order of Officer of Public Instruction by the French Republic; Oral Surgeon to St. Joseph's, Michael Reese and Other Chicago Hospitals; Consulting Oral Surgeon Presbyterian Hospital, etc. With special chapters by MATTHEW H. CRYER, M.D.; G. HUDSON MAKUEN, M.D.; WILLIAM J. YOUNGER, M.D.; F. W. BELKNAP, M.D., and CALVIN S. CASE, M.D., D.D.S. Price, cloth, \$10.00 net. Philadelphia: P. Blakiston's Sons & Co., 1915.

At first glance one is amazed at the bulk of this book, but on clear examination one sees that this is accounted for mainly by the extremely exhaustive manner in which the various subjects have been treated. There has seemingly been an effort to compile everything in the literature bearing upon this subject that is of any importance, as is shown by countless direct quotations and still more numerous references to the opinions or methods of this or that writer or operator. With the exception of the chapters devoted to hare lip and cleft palate, occupying something over 200 pages and in which Brophy's methods and views are set forth at great length, the author's personal contributions are rather overshadowed by the wealth of borrowed material. It is very evident, however, that he has spent

a great deal of time and care in the preparation of this work and has not hesitated to call to his aid others whom he considered better informed in certain special topics of importance to the oral surgeon; hence the work is rendered still more authoritative and covers the field most thoroughly.

While some of the reproductions from x-ray plates are bad and there are many illustrations, particularly of instruments in common use, that seem unnecessary, the greater part of the illustrations and colored plates are well chosen and add much to the value of the book. As a whole, the work is one that the general surgeon as well as the oral specialist will find well worth while.

PROGRESSIVE MEDICINE. A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by HOBART AMORY HARE, M.D., Professor of Therapeutics, Materia Medica and Diagnosis in the Jefferson Medical College, Philadelphia; Assisted by LEIGHTON F. APPLEMAN, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. December 1, 1915. Price, \$6.00 per annum. Philadelphia and New York: Lea & Febiger.

THE current number of *Progressive Medicine* contains chapters on Diseases of the digestive tract and allied organs, the liver, pancreas, and peritoneum, by Edward H. Goodman; Diseases of the kidneys, by J. Harold Austin; Genito-urinary diseases, by Charles W. Bonney; Surgery of the extremities, shock, anesthesia, infections, fractures and dislocations, and tumors, by Joseph C. Bloodgood; and Practical therapeutic referendums, by H. R. M. Landis. A noticeable feature of the present number is the large amount of space devoted to military surgery. We miss the contribution of Dr. John Rose Bradford, whose articles on Diseases of the kidneys have been a feature of the December number of this quarterly since 1899.

PRACTICAL PRESCRIBING AND TREATMENT IN THE DISEASES OF INFANTS AND CHILDREN. By D. M. MACDONALD, M.D., F.R.C.P.E. Price, \$1.50. London: Henry Frowde, Oxford University Press; Hodder & Stoughton; New York: Oxford University Press, American Branch, 1915.

THE author announces in the preface of this little manual that it is a mere truism to state that the faculty of prescribing for infants and children presents special difficulties. These difficulties are overcome in this book, which, published in a compact form and easily carried, gives the rational treatment of all the diseases of childhood, as well as a brief chapter on infant feeding. There are a dosage table and a diet table, a chapter on emergencies, formulæ, a therapeutic index, and an extensive chapter on tuberculin and the tuberculous child.

DISEASES OF THE NOSE, THROAT, AND EAR. By WILLIAM H. KELSON, M.D., B.S., F.R.C.S. (Eng.), Surgeon, London Throat Hospital, Golden Square; Hon. Surgeon (in charge of Throat, Nose and Ear Department), City Dispensary; Lecturer on Diseases of the Ear, Polyclinic. Price \$3.00. London: Henry Frowde, Oxford University Press; Hodder & Stoughton; New York: Oxford University Press, 1915.

THE book is written "for general practitioners and senior students." It is an earnest effort to cover in simple form the many abnormal conditions of the nose, throat and ear, and to give treatments which the general practitioner can carry out. Operative treatments are given briefly. Some wise warnings are offered, among others, are those in regard to tonsil operations, the possible mishaps and reasons for bad results.

There is adequate emphasis on the need for early diagnosis in diphtheria. Kelson names "a bacteriological examination" as one of the methods "to enable us to arrive at a correct diagnosis" in acute tonsillitis, but after discussing treatment and the exhaustion which follows an acute tonsillitis, he says: "Should paralytic symptoms supervene affecting the eye, palate, etc., the practitioner may conclude that his patient has been suffering from diphtheria." One would scarcely consider this a true method for diagnosis. Under the discussion of laryngeal diphtheria also, one is led to feel that a correct diagnosis is fortunate, not an absolute necessity, and no mention is made of treatment with antitoxin.

Since the connection between tonsillitis, rheumatism, and endocarditis is so clearly recognized, more emphasis might wisely be placed on such a connection in a discussion of acute tonsillar infection—not a mere mention that it is "doubtless associated with rheumatism, often preceding rheumatic fever."

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 26, 1915.

DR. LEROY BROWN IN THE CHAIR.

Five Cases of Ureteral Fistula.—Dr. HENRY DAWSON FURNISS presented this report. He stated that in each instance the ureteral fistula had followed hysterectomy. In the first case, four weeks after the first operation the patient had both ureters implanted into the bladder by the abdominal route transperitoneally. The ureters were found to be about the size of the little finger and much indurated. Following this operation, the patient developed pneumonia and on the eighth day coughed the wound open, the intestines escaping. These were replaced and the patient then made an uninterrupted recovery. An examination made a few weeks after this operation showed the ureters projecting into the bladder about one-half to three-quarters of an inch. When last seen they projected only one-eighth of an inch. The point of interest in this case was the thickness of the ureters as observed a short time after the primary operation. In the second case the ureteral fistula involved only the left ureter. The fistulous opening was anastomosed into the bladder by a plastic operation through the vagina. Later, examination showed that the fistulous opening was discharging pus in large amounts. The ureter was then implanted into the bladder directly. Subsequently it became necessary to remove the left kidney, it being about one-third the normal size, with calyces much dilated and atrophy of the renal parenchyma. The ureter was the size of a lead pencil, dilated and thickened. This case taught that the patient should have been operated on very soon after the occurrence of the injury to the ureter and that the ureter should have been implanted into the bladder by an abdominal operation. It also taught that it was a mistake to anastomose the end of the fistulous tract into the bladder instead of anastomosing the ureter into the bladder, and the third operation should not have been an anastomosis of the ureter into the bladder, but should have been a nephrectomy at that time. The ureteral fistula in the third case followed an exceedingly difficult hysterectomy for fibroids of the uterus. In this instance it was deemed advisable to remove the kidney rather than to attempt to anastomose the ureter into the vagina. The removed kidney showed marked evidence of pyelonephritis with dilatation of the ureter and of the calyces of the kidney. If a ureteral anastomosis into the bladder had been made it was doubtful if this kidney would have resumed its function. In the fourth case it was determined that the injury was on the right side. A transperitoneal ureteral vesical anastomosis was made. This patient died three days afterwards from a general pelvic peritonitis. The point of interest in this case was that the kidney function was well preserved after several weeks. This was particularly to be noticed in those cases in which the injury to the ureter was a lateral injury and not where the ureter was completely divided. In the fifth case there was a discharge of urine through the abdominal wound, following an abdominal hysterectomy. Cystoscopic examination showed that there was no urine coming from the left ureter. When this patient was seen again a week later there was no urine coming from the abdominal wound and no discharge of urine into the bladder on the left side. This case illustrated the fact that in the uretero-abdominal fistulas the contraction of the long fistulous tract became complete and the kidney became inactive from the exclusion of the ureter. This patient was lost sight of and the subsequent history was therefore unknown.

Ruptured Ectopic Pregnancy Simulating Pelvic Infection.—Dr. ANTHONY H. HARRIGAN reported this case. He said that the patient was a woman 26 years of age, who had had one child that died of cretinism at the age of two years. Her last menstrual period had occurred June 5, 1915. The menstrual period did not take place in July. The patient was admitted to Fordham Hospital on August 12, stating that her illness began three weeks previously with severe pain in the right lower quadrant of the abdomen. She had had several attacks of pain before her admission to the hospital and a bloody vaginal discharge since two weeks

before. The physical examination at the time of admission showed marked rigidity of the lower one-half of the right rectus muscle, associated with extreme tenderness over McBurney's point. While the uterus could not be mapped out accurately because of its extreme tenderness, its immobility was determined. A solid mass could be felt on each side of the uterus. The findings were characteristic of double tubal pregnancy. The patient's temperature was 100.6° F., pulse 36, and respirations 32. There was a leucocytosis of 15,200 with 77 per cent. polymorphonuclears. A diagnosis was made of pelvic infection of tubal origin, associated with secondary appendicitis. At operation on August 23, eleven days after admission, the abdomen was opened through a mesorectal incision. Upon entering the peritoneal cavity a fair amount of old blood clots escaped. The sigmoid was firmly attached to the pelvic organs. After freeing this the tubes and ovaries were found deeply imbedded in the pelvis. A large dense, black blood clot lay embedded between the rectum and the posterior surface of the uterus. The right tube showed a ruptured ectopic pregnancy. The appendix was tightly stretched across the brim of the pelvis and was markedly inflamed. A right salpingo-oophorectomy, a left salpingectomy, and an appendectomy were performed. The patient made an uneventful recovery. The error in this case was made by not laying sufficient stress on the absence of menstruation in July.

Hemorrhagic Pelvic Peritonitis.—Dr. ANTHONY H. HARRIGAN reported this case, which occurred in a woman thirty-four years of age, who was admitted to the Fordham Hospital on August 13, 1915. Her present illness began three weeks before admission with severe pain in the lower quadrants of the abdomen. Seven days after the onset of the pain she was subjected to dilatation and curettement. At this time the left tube was found thickened. At the time of admission to the hospital a diagnosis of pelvic abscess was made. Pelvic examination showed a uterus tender and fixed and also a tender mass behind and lateral to the uterus. The patient was kept under observation and treated conservatively until August 25, at which time an operation was performed. The findings were almost identical with those of the preceding case. Owing to the condition of the uterus a supravaginal hysterectomy was done. The appendix was also removed. Dr. Norris, the pathologist, reported that the uterus was not punctured, but that it was enlarged and showed inflammatory exudate on the serosa. There was hemorrhagic cellulitis and perimetritis and also a chronic interstitial salpingitis, a large corpus luteum cyst and chronic obliterating appendicitis. This case was reported in conjunction with the first because of the great similarity of the operative findings. It would be interesting to know the cause of the hemorrhage in the second case.

Ruptured Interstitial Ectopic Pregnancy, Complicated by a Large Ovarian Cyst; Ovariectomy and Hysterectomy.—Dr. ANTHONY H. HARRIGAN reported this case. He stated that the patient was admitted to the Fordham Hospital September 16, 1915. She had never been pregnant, though married two and one-half years and desirous of having a child. Since March 15 she had had frequent menstruation, lasting about the usual four days. Her general health continued good until August 1, when she had her last menstruation. From this time until her admission to the hospital she had at times twinges of pain in the right lower quadrant of the abdomen and slight momentary nausea. On the morning of the day she was admitted she was seized with acute stabbing pain in the lower right quadrant, felt nauseated, weak and faint. There was no flow of any kind. Eight hours after the onset of these symptoms the patient presented the typical appearance of internal hemorrhage. A diagnosis of ectopic pregnancy was made. At operation on opening the peritoneum through a median incision, a large amount of free blood escaped. Further examination revealed a large ovarian cyst, springing from the left side and filling the entire abdomen up to the liver. Upon incising the cyst a large amount of fluid escaped and the cyst collapsed. It was then easily removed. Inspection showed a neglected ectopic in the region of the right horn. A supravaginal hysterectomy was performed. An intravenous injection of 700 c.c. of saline solution was given during the operation. The patient made a prompt recovery and was discharged in good condition. Dr. Norris had reported a simple ovarian cyst and a ruptured ectopic pregnancy. The specimen was interesting in that there was a walnut-sized dilata-

tion of the uterine end of the tube. The considerable amount of the organization of the hemorrhage confirmed his belief that the pregnancy was of the interstitial type.

Dr. THOMPSON T. SWEENEY said that the history of the first case pointed towards a diagnosis of the condition found at operation. The leucocytoses and the high temperature were found present in ruptured ectopic due to the reaction of the peritoneum to the extravasated blood. In the second case the inflammatory condition was probably due to infection at the previous curettage. The question as to the cause of the presence of blood was an interesting one. Might it not have been an unexpected tubal abortion or blood from torn adhesions produced by injury at the time of curettage?

Dr. ANTHONY H. HARRIGAN said Dr. Sweeney's explanation of the hemorrhage was plausible, but in this instance there was more blood than could be accounted for by the rupture of adhesions. As for himself, he was at a loss as to how to explain it.

Vaginal Cesarean Section (Two Cases).—Dr. ARTHUR STEIN reported these cases. He stated that these two cases were interesting because they showed what could be done with vaginal cesarean section and what should not be done with it. The first case occurred in a woman 28 years of age, who was admitted to the Harlem Hospital on September 24, 1915, during the fourth month of her pregnancy. She had been vomiting for three or four weeks previous to her admission and could retain no food. Twenty-four hours before her admission she had had two convulsions and had marked mental confusion. The boiled urine was practically solid with albumin. Immediate surgical interference was indicated and the Dührssen operation decided upon. Before proceeding with this operation it was advisable to inject one c.c. of pituitrin subcutaneously, which permitted of a practically bloodless procedure. The toxemia was so severe that even five days after the operation the patient was unable to retain any food, except small quantities of milk. However, she gradually improved, the urine cleared up, and she left the hospital on about the eighteenth day. The urine still showed some casts. The second case was that of a woman who had a unilateral fused kidney that was easily palpable. A report of this case had appeared in the *American Journal of Obstetrics* in 1913. The pregnancy showed nothing abnormal, except that the patient had been bleeding occasionally for the past month, when Dr. Stein was called to see her. The possibility of placenta previa suggested itself. Examination of the patient showed the head of the child on the left iliac fossa and showing no tendency to engage. The small parts and the breech were to be felt on the extreme right side underneath the ribs. The cervix admitted one finger and one could make out some spongy mass above the internal os. About two hours later the patient had another hemorrhage. She was at this time very anemic and there was no dilatation of the cervix. An immediate vaginal cesarean section was therefore decided upon. This was easily accomplished except for the extraction of the head, which was arrested through some obstacle and required some time for extraction. The child was born dead. There was a tremendous hemorrhage and the uterus showed no tendency to contract. In spite of injections of camphor and ether and the infusion of saline solution, the patient died two hours after confinement from extreme anemia. It might be possible that the unilateral fused kidney on the right side was the cause of the head not entering the pelvis and of its being arrested on the iliac fossa. Had this been considered before the operation a vaginal cesarean section would never have been done, since in all probability an abdominal operation could have been performed with greater success. The rule had now been adopted at the Harlem Hospital that a vaginal cesarean section be done in all cases in which cesarean section is indicated up to the seventh month, and that after that time the abdominal section was indicated.

Gangrene of the Lower Extremities after Gynecological and Obstetrical Operations.—Dr. ARTHUR STEIN made this report in which he stated that all obstetricians had seen cases of thromboses and emboli, but very few even of the busiest obstetricians had seen cases in which these conditions had led to complete gangrene of one or two extremities during pregnancy or the puerperium. Two such cases, however, had come under the observation of the writer at the Harlem Hospital, and strange to say, practically at the same

time. The first patient was a young woman, 20 years of age, who shortly after her admission to the hospital on June 9, 1915, aborted a three months' fetus. The patient's temperature which was 104° F. at the time of her admission dropped to normal on the day following the abortion but again rose and continued high until the seventh day, when it was decided that curettage was indicated as the uterus was still enlarged and soft. Examination revealed numerous grayish-white superficial ulcers around the cervix. After the curettage, at which considerable placental tissue was removed, the whole interior of the uterus, as well as the cervix, was swabbed with tincture of iodine, and this was repeated daily for the next seven days. Even after the curettage the temperature did not become entirely normal. About a week after the curettage the patient began to complain of pain in her right leg and three days later the right leg began to swell, became cold, and showed a purplish discoloration. Pulsation of the artery of the foot could not be felt. Seven days from the time the patient began to complain of pains in her leg gangrenous spots about one-half inch wide appeared above the previous line of demarcation. There was no improvement whatever in the condition of the foot. Inflammation was extending along the external side of the leg about 4 inches above the discoloration. The vaginal discharge was very much decreased. The patient was finally transferred to the surgical ward and the leg amputated below the knee on July 29. The patient made an uneventful recovery. A histological examination of the part removed showed that there was thrombosis of the peroneal artery, necrosis of the skin and superficial fascia, necrosis of the muscle, and periostitis of the fibula. This case was of extreme interest because, so far as the writer could find, it was only the third case on record in which gangrene set in after abortion. The outcome in the second case was not so fortunate as in the first. This patient was a young woman, 19 years of age, who was admitted to the Harlem Hospital in generally good condition on June 12, 1915. On June 14 she was delivered with forceps, after a double episiotomy had been performed. The child was dead. The episiotomy and second degree laceration were repaired. Two days after confinement the patient had a temperature of 104.5° F. and a slight chill. On examination some slight ulcers were found around the cervix for which the patient received the ordinary treatment. On the sixth day the sutures were removed because the whole area was sloughing. Ten days after confinement, she still had irregular temperatures and appeared to be very ill. Twelve days after confinement the patient left the hospital against advice, only to return on July 3, five days later, in a critical condition. Both lower extremities for a distance of about 4 inches above the ankles were discolored bluish black, were extremely tender to the touch, cold, and in some places showed rather large vesicles filled with white fluid. There was no difficulty in making a diagnosis of gangrene of both feet. The patient's general condition of extreme exhaustion and debility did not permit of operative interference and she died on July 19. It was impossible to get an autopsy in this case. As an explanation of the symmetrical gangrene the writer advanced the theory that a thrombus left the uterus and migrated into the uterine artery, thence into the internal iliac and the common iliac up to the bifurcation of the aorta, where it also occluded the other common iliac artery, and by so doing caused a symmetrical gangrene on both sides. There were few cases on record in which gangrene occurred during the puerperal state (60 to 70), and in only a few were the upper extremities affected.

Dr. HERMANN J. BOLDT said that as to the vaginal cesarean section it seemed to him that in primiparæ at the seventh month the abdominal operation was preferable. Personally he felt that the vaginal operation was productive of considerable trauma, and he always felt that he ought to make an extensive paravaginal incision to insure satisfactory delivery. During the past summer, Dr. Boldt said he had seen a case of gangrene following a radical operation for cancer of the uterus. In this case the gangrene was limited to three toes. Discoloration was present for two weeks and he thought the toes would have to be amputated. However, the patient recovered without operation.

Dr. ASA B. DAVIS said he had seen the cases of gangrene that Dr. Stein had just reported. In his hands he had found vaginal cesarean section a difficult operation and he had watched some of the men who

claimed that it was easy to perform the operation, but in watching them he was not impressed that it was easy. He did not think a vaginal cesarean section should be done in any case in which the child had reached considerable size; the abdominal route was much safer, especially in primiparæ. As to the case with hemorrhage, in which there was hemorrhage with the cervix closed and the woman not in labor, the hemorrhage was either due to placenta previa or was from the placenta, and the woman should not be allowed to have more than one such hemorrhage. In reading up the literature on this subject, Dr. Davis said it was noticeable that when obstetricians did not wait after such hemorrhage, but operated promptly the results were much better than when a waiting policy was followed.

Dr. ABRAHAM RONGY expressed the opinion that vaginal cesarean section was a suitable operation during the earlier months of pregnancy, but that at the seventh month it was difficult and after the seventh month it was likely to give one a great deal of trouble. In the second case in which there was a placenta previa hemorrhage a vaginal cesarean section should not have been done. As to the postoperative gangrene, two cases had come under his observation; one of these occurred eleven days after a pubiotomy in a general hospital and the patient died without having been operated upon. The other case followed a placenta previa. This patient developed a pneumonia also and died on the seventeenth day. Curetting a uterus that was in a septic condition was a bad practice.

Dr. ANTHONY H. HARRIGAN asked Dr. Stein whether he had blood cultures taken in those cases.

Dr. O. P. HUMPHSTONE of Brooklyn said he wished to say a word in defense of vaginal cesarean section. They at present had a living baby as the result of a vaginal cesarean section performed at the eighth month of pregnancy on a patient in uremic convulsions. Vaginal cesarean section could be performed at the seventh or eighth month if the baby was not large and if the anterior section was employed.

Dr. LEROY BROUN said that he could recall but one case of post-operative gangrene. This patient died. She was not one of his own cases and he did not recollect what operation had been performed, but he recalled that the patient had a gangrene of the foot and that it continued to ascend. She had two operations, but they were not successful in checking the disease.

Dr. ARTHUR STEIN said that he agreed with almost all that had been said with reference to vaginal cesarean section, and he had reported the second case only because it was unsuccessful. There was, however, a wide field for cesarean section, as in cases in which the uterus was already infected, but one had to be sure of his technique. As to what had been said about leaving infected cases of abortion alone, he knew that many gynecologists were treating these cases without operative interference. It was planned at the Harlem Hospital to treat a series of infected incomplete abortions conservatively, and a series operatively, so as to be able to compare the results in both series. In answer to Dr. Harrigan's question, Dr. Stein said that cultures from the womb had been taken but they only showed mixed infection, streptococcus, staphylococcus, etc. It was not feasible to make a culture from the thrombosed vessels, and the state of the amputated leg was such that it was not feasible to make a culture.

Fibrocyst of the Ovary with Suppurating Tubo-Ovarian Cyst on Opposite Side.—Dr. HERMANN J. BOLDT presented this specimen, taken from a patient thirty-seven years of age, who had never been pregnant. It should be borne in mind that nearly 2 per cent. of ovarian tumors were fibroids, and that a number of tumors that at first sight impressed one as being fibroids on histological examination revealed a sarcomatous structure. The occurrence of a fibroid ovary in which the larger part of the tumor was to all appearances a true ovarian cyst in structure was comparatively rare. This tumor weighed originally 2200 grams. No malignant changes were found. The other tumor was a large pyosalpinx, and the ovary was transformed into a cystic tumor.

Four Uteri the Seat of Chronic Inflammation.—Dr. HERMANN J. BOLDT presented these specimens. The women from whom they were removed were between forty and forty-five years of age and had had very profuse and typical bleeding from one to four years, which resisted all other treatment. It was to be noted that in three cases the uterus was increased from double to three times the normal size, so that in two

of the cases the mistaken diagnosis of probable adenomyoma was excusable. Indeed, they showed small myomata in the uterine muscularis. All showed the characteristic increase of connective tissue and an increase in the muscularis of the blood vessels. While in the fourth case the size of the uterus was not so much increased, the organ was so globular as to almost resemble a ball. In the case of younger women such radical treatment was not carried out, but intrauterine applications with zinc chloride were tried.

Adenocarcinoma of the Uterus and Carcinomatous Gall Bladder.—Dr. HERMANN J. BOLDT presented this specimen, which had been removed from a woman forty-four years of age. After removing the uterus, the general abdominal cavity was explored and the gall bladder was removed because of the carcinomatous appearance macroscopically. Subsequent microscopic examination verified the suspicion. Undoubtedly in this instance the uterine cancer was a metastasis from the gall bladder. Quite frequently ovarian cancer was a metastasis from the stomach or gall bladder, but uterine adenocarcinoma, as a metastasis from the gall bladder was not of such frequent occurrence.

Myofibromatous Uterus.—Dr. HERMANN J. BOLDT presented this specimen, which had been removed from a patient forty-six years of age who had had one pregnancy five years previously, but aborted at the third month. The pelvis was tightly impacted by a solid tumor in this case. It was with difficulty that fibromyomatous tumors could be dislodged with a corkscrew tractor. The pathologist's report showed a repetition of what he usually found, which was contrary to the findings usually reported, namely, almost invariably he had found that myoma was accompanied by an endometrial inflammation, and also that the greater number of these patients had a catarrhal inflammation of the appendix. Some operators reported just the contrary.

Intermediate Trachelorrhaphy.—Dr. HERMANN J. BOLDT read this paper. He said it was not likely that any one doubted that extensive lacerations of the cervix during childbirth might do much harm, nor that occasionally they might favor the causation of cancer. Did it not behoove them, if only as a prophylactic measure, to repair cervical tears, and to do this before pathological changes incident to the trauma manifested themselves? Dr. Boldt purposed to plead for such procedure, and especially that it might be done when the sacrifice of material tissue was not a necessity. His justification lay in the fact that those who had made a careful study of the results of cervical tears almost invariably verified the assertion made by Dr. Thomas Addis Emmet concerning their deleterious effects. In support of this he called attention first to the careful study of Brooks Wells made from the clinical material of the late Paul F. Mundé, and then to a paper read by Clement Cleveland before the New York Obstetrical Society. What these papers stated then held good to-day. The analyses made by the authors cited he could multiply several times from his own practice having, before and since then, seen thousands of lacerated cervixes from which he could verify the position taken by these writers. Resulting ills had been exaggerated by some physicians, but this applied to most matters, everything depending on the point of view. Some indeed had gone so far as to say that every laceration required repair. Dr. Boldt had seen many patients with slight tears who had been told that they must have the laceration repaired, although they had existed a long time, too long to do an operation without denuding the torn edges by cutting away tissue, and were causing absolutely no trouble. It was not his purpose to dwell on the pernicious effects that lacerations might cause, but rather to call attention to a slight operation, to be applied in properly selected instances, whereby eventual ailments due to such injuries might be prevented. He did not claim that all lacerations were productive of pathological changes; neither did he claim that there was any time limit as to symptoms showing themselves after the injury. According to Cleveland the average time in his cases was four years and six months; but this might be shorter. Some held that tears should be closed immediately after delivery, but it would be conceded that this was not practical or necessary, except in cases of hemorrhage from an exceptionally extensive tear. It was far better to wait until the effect of contusion had passed off and bleeding had ceased, so that one might inspect with exactitude. Moreover, many small tears healed spontaneously post partum. After, say from four to six

weeks post partum, however, the genital tract should be inspected, particularly in primipara, because for these the operation was particularly intended, and if a tear of some extent was found, it should be repaired. His present method of repair was simple, so simple that anyone with a little surgical ability could easily adopt it. The patient was placed in the lithotomy position and the customary disinfection attended to. If she was not hypersensitive and not nervous, no anesthesia was required, for the operation was not very painful. The cervix was pulled down with a pair of well-working bullet forceps, and exposed with vaginal retractors. The bullet forceps were then adjusted, one pair in the line of the cervical canal on the anterior lip, and one pair similarly applied on the posterior lip. With a narrow but very sharp scalpel, sharp especially at the point, a superficial film of tissue was scraped off the torn surface, taking particular care that the angles of the tear were made raw. For sewing he usually used a full-curved medium-sized Martin needle which had cutting edges; but one might use any other needle if more accustomed to it. A No. 2 chromic catgut was passed so as to include the entire depth of the tear. Usually two sutures sufficed for each side of the tear. Sometimes only one suture was required for one side, it frequently being the case, in instances of bilateral tear, that the tears were unequal in extent on the two sides. This also held good for stellate tears. Care should be exercised in tying. The surfaces should be brought together just snugly, never too tight, so that the sutures might not cut into the tissue. No after-treatment was necessary, and the patient might be about as usual after the operation. It would be seen from the foregoing that the operation was not applicable to any case in which the tear had existed long enough to cause pathological changes, in which scar tissue was present in the angles. In all such patients the scraping, or making the torn edges raw, did not suffice. That was why he said it was particularly applicable for primiparae who had not previously sustained a tear, and that in the case of every primipara it should be a part of the accoucheur's duty to make a visual inspection in about four to six weeks subsequent to delivery, and then to repair any existing laceration (unless it was of negligible extent) in the way outlined. It was understood that in scraping the edges scrupulous care should be taken to avoid the mucosa of the cervical canal.

Dr. THOMPSON T. SWEENEY said that experience had taught them the futility of immediate repair of the cervix. If Dr. Boldt's results were as he stated, his procedure was to be recommended, if only to save the patient from the formation of scar tissue with possible subsequent cancer involvement. Lacerations of the cervix unless they were so deep as to interfere with the retentive power of the uterus, produced no symptoms save where scar tissue was present. The erosions so frequently seen and blamed on the lacerations were not necessarily caused by the lacerations, since the same condition was found in virgins and was due to the constant leucorrhoeal discharge.

Dr. GEORGE W. KOSMAK related that some years ago at the Lying-in Hospital one of the members of the staff was working up the subject of the immediate repair of the cervix and conscientiously sutured up all the tears. It was observed that these patients usually showed an elevation of temperature within twenty-four to thirty-six hours; this was due to insufficient drainage of the uterus. At this time he was much interested in this work and made it a practice to inspect all his private cases. He had found that, even where there was a laceration that looked very dubious immediately after labor, four weeks later it had largely disappeared. If one remembered that in the event of a subsequent labor the cervix was likely to be torn in the line of the former repair, one might hesitate a little before making such repair. More damage occurred from the absorption of infectious material than from slight laceration, and hence, wherever one had a raw surface it should receive proper treatment. As to the danger of scar tissue as a focus for future malignant disease, this might be attended to in an intermediate stage and should be in women likely to have more children.

Dr. BOLDT, in closing the discussion, said that by an intermediate operation he meant one performed after the immediate effects of labor had passed and before any pathological changes had taken place in the cervix. After such changes had taken place trachelorrhaphy was not indicated. If at future delivery a tear occurred

in the line of the former repair one could sew it up again, as the operation as he had described it was a perfectly simple one.

SECTION ON PEDIATRICS.

Stated Meeting, Held November, 11, 1915.

DR. WALTER LESTER CARR IN THE CHAIR.

A Simple Outfit for the Distribution of Diphtheria Toxin.—Dr. ABRAHAM ZINGHER presented this apparatus. He stated that in a series of 800 children who reacted negatively to the Schick test and a considerable proportion of whom were exposed to diphtheria, not a single child had developed the disease. They therefore felt confident that a negative reaction meant immunity, while a positive reaction indicated a probable susceptibility to diphtheria. In recent experiments as to the duration of immunity, they had found that after the usual 1,000 units of diphtheria antitoxin the immunity lasted from fourteen to twenty-one days, while after a second dose of similar size immunity lasted only from seven to ten days. They had also found that in those naturally immune an immunizing dose produced greater immunity. Some of their recent experiments with the toxin-antitoxin mixture showed that an active immunity did not develop soon enough to be of value in giving immediate protection in the wards of a contagious hospital, but that many who did not become immune at first later developed immunity. The outfit presented was devised to overcome the difficulties that had stood in the way of popularizing the Schick test; namely, that the diluted toxin rapidly deteriorated whether kept in solution or in tablet form. This outfit furnished a standard amount of undiluted diphtheria toxin, which remained of fairly constant strength when kept in the ice-box, and could be readily diluted when required. The operator who attempted to use it should be skilled in the intracutaneous method of making the injection, and should consider all reactions true unless he was able to distinguish the positive from the pseudo-reaction. The pseudo-reaction appeared earlier, was less sharply circumscribed, and usually disappeared in from three to four days. It was characterized by a central area of redness of varying size surrounded by a secondary areola. On fading it left only a faintly pigmented area, which soon became invisible. The true reaction persisted for several weeks. This outfit consisted of a capillary tube containing two minimum lethal doses of diphtheria toxin for the guinea pig, and a bottle containing 10 c.c. of sterile physiological saline solution (with 0.025 per cent. phenol). This toxin should not be a freshly prepared lot, but should be ripened for at least a year. In using the toxin, the one end of the capillary tube was broken off and pushed carefully through the neck of the rubber bulb until it punctured the diaphragm within, and entered the cavity of the bulb; then the other end of the tube was broken off. Holding the bulb between the thumb and middle finger and placing the index finger over the opening in the larger end of the bulb, the toxin was expelled into the saline. The capillary tube should be rinsed out by drawing up saline several times. The bottle was then corked and shaken. Exactly 0.1 c.c., representing one-fiftieth of the lethal dose for the guinea pig, was then injected intracutaneously on the flexor surface of the forearm. The contents of the bottle were sufficient for about eighty tests. On account of the fairly rapid deterioration of the diluted toxin, it was not advisable to use it after about twelve hours. A 1 c.c. record tuberculin syringe and a fine platinum iridium needle, No. 22, or a steel needle, No. 3, were to be preferred. An ordinary hypodermic syringe, unless graduated to 0.1 c.c., was not satisfactory.

The Chemistry of Cow's Milk and Other Products Used in Infant Feeding.—Prof. F. W. HOWE of Boston presented this paper by invitation. He stated that he had very little that was original to present, that not being the object of the paper, but that he had endeavored to compile the somewhat voluminous literature of this subject in such a way as to be of practical value to the busy practitioner. After giving the chemical composition of cow's milk according to Van Slyke and Bosworth, he stated that this percentage composition was influenced by a number of factors chief among which were the breed of the cow, its health, stage of lactation, and the feed that the animal was receiving. The composition of milk was also influenced by physi-

cal, chemical, bacteriological, and physiological means after it was drawn from the cow. Among the physical changes were alterations in odor and flavor due to feeding strong herbs and vegetables, changes by manipulation, as by the use of the homogenizing machine by which the fat globules were broken into much smaller ones, so that they would remain in suspension for weeks with no cream line appearing, and changes by heat. In discussing the changes in composition brought about by chemical means the author reviewed the action of lactic acid, lime water, sodium bicarbonate, sodium citrate, and milk of magnesia. He pointed out that there were about three hundred varieties of lactic acid bacilli, and that each one exerted its own peculiar action on the casein. In discussing the composition of milk as influenced by bacteriological means, the writer considered the fermentative and the putrefactive types of bacteria. He stated that according to Kendall and his associates it could be stated almost as a biological axiom that under natural conditions fermentative actions almost invariably preceded putrefactive actions. This being true, the souring of milk coming first gave us a natural danger signal to warn us of what might come later. The composition of milk as influenced by physiological means led them to the study of the natural ferments and their enzymes, the diastases, lipases, catalases, peroxidases, and reductases. Each one of these had its own specific action on the constituents of milk, fulfilling its function in the part of self digestion. The author then reviewed the chemistry of milk sugar, malt soup, dextrimaltose, sucrose, dextrose, cereal jellies, protein milk, protein milk plus lactic acid milk, whey, and proprietary foods. In discussing the composition of proprietary foods, Dr. Howe stated that all were familiar with the fact that it was difficult to keep fats sweet and wholesome, and while it was not so difficult to keep the proteins, it was no easy matter. This narrowed the field very considerably when it came to making proprietary foods, with the result that most of them were made of blended carbohydrates. These foods had been admirably treated in Holt's book in which an analysis of the principal proprietary foods was given. This analysis Dr. Howe presented.

The Digestibility of Cow's Milk Protein and the Use of the Protein Milks.—Dr. L. EMMETT HOLT presented this paper in which he said that clinical and laboratory researches of the last ten years had greatly modified our views regarding the proteins in infant feeding. It was not many years since the difficult digestion of the protein of cow's milk was looked upon as the important, probably the chief, cause of their troubles in infant feeding. Metabolism experiments made at the Babies' Hospital and in many other places had revealed the fact that under almost all circumstances infants possessed a remarkable capacity for retaining nitrogen. Even in conditions of severe malnutrition the protein of cow's milk was well borne, as shown by a positive nitrogen balance even though the infants were losing weight. Clinical evidence also of the infant's tolerance of protein was not wanting. At present they could mention no symptom or group of symptoms which could be positively attributed to the proteins in the sense that definite symptoms could be attributed to the fats or carbohydrates. However, it was pertinent to inquire whether the present practice of giving much higher proteins than formerly was to be recommended without reservation, or whether it was possibly injurious. Taking the composition of woman's milk as a guide it was found that it contained 3.5 per cent. fat, 7.5 per cent. sugar, and 1.25 per cent. protein; thus a nursing infant was receiving a little over 7 per cent. of his calories in the form of protein. An artificially fed infant taking cow's milk one-half strength with sufficient sugar added to bring the carbohydrates up to 6 per cent. is receiving over 14 per cent. of his calories in proteins. In their metabolism experiments they had shown that with high protein feeding there was at first a marked increase in nitrogen retention, but that this persisted for only a short time, and that increased intake was followed by increased excretion, which was nearly but not quite proportional. Rubner believed that the excess of nitrogen taken could be used up in the place of other food elements. Evidence had been brought forward showing that the protein of cow's milk when given in considerable excess of the needs of the body might bring about disturbance of metabolism causing clinical symptoms of importance and even of gravity. But such symptoms were seen only when protein was given much in excess of the amounts commonly

employed. Experiments along this line, while not conclusive, were strongly suggestive of possible harm from very high protein feeding. The latest studies of the food proteins had indicated that the amount of protein given was much less important than the nature of the protein furnished. The amino acids, dysin, cystin, tryptophan, and glycocoll, were of great importance. It did not seem possible for nutrition to go on unless the first three mentioned were present in the food; there was good reason to believe that glycocoll could be produced in the body by synthesis. As to the bearing of this on infant feeding,—animal proteins were rich in essential amino acids, while many vegetable proteins were deficient in them. Lactalbumin was one of the animal proteins that contained the essential amino acids in the largest proportion. Casein was, however, notably deficient in cystin. The deficiencies of casein were ordinarily made good by lactalbumin. It surely was not an accident that woman's milk had twelve times as much lactalbumin as cow's milk. Nature had not intended the milk of the cow to nourish the calf for a long period, since the maximum excretion of cow's milk was about the second month, after which it steadily declined, the calf at birth had six teeth and at six weeks from twelve to sixteen teeth, indicating his capacity for other food than milk. The secretion of woman's milk increased until the seventh or eighth month and the infant did not get his teeth until this time, suggesting that up to this time other food was unnecessary for normal nutrition. In artificially fed infants the conditions are different, and they had lately seen the advantage of feeding other articles of diet, fruit juice, egg, broth, and even fresh vegetables. In this way they had been supplying the deficiencies of cow's milk. The success which had attended the use of formulas made from whole milk had not been entirely due to the fact that fat disturbance had been avoided, but that in these formulas by increasing the protein they had come nearer supplying the infant's actual amino-acid needs. The writer stated that in his experience in acute intestinal disturbances it was the carbohydrates that were most frequently the exciting cause, and sugars were even more badly borne than starches. Milk sugar seemed to cause more disturbance than any other form of carbohydrate. It was for such cases that Finkelstein's milk modification was so valuable. Its usefulness was seldom enhanced by preparing it from skimmed milk, but rather the contrary. Its relatively high fat was tolerated without difficulty when very low sugar was given. However, this preparation should be regarded as a therapeutic agent and not a method of infant feeding. These newer facts regarding the proteins were bound to have an important influence in their future study, not only of the rôle of protein in infant feeding, but in making clear the fundamental protein requirements in nutrition and in opening up a new field for investigation in the problem of artificial feeding.

Present Opinions as to the Rôle of Fat in Infant Feeding.—Dr. JOHN LOVETT MORSE of Boston presented this phase of the subject. He stated that the fat in infant's food was chiefly in the form of neutral fat. The amount of digestion upon it in the stomach was therefore unimportant. The real digestion of the fat took place in the small intestine, where it was split into fatty acids and combined with alkaline carbohydrates to form soaps. Fat was largely if not entirely absorbed in the form of soap in all probability. Neutral fat was not absorbed. The absorption of fat was extremely good in health, more than 90 per cent. of the fat ingested being absorbed whether the food was human or cow's milk. Little was really known of the significance of the fatty acids and soaps. Fatty acids were irritating to the intestines; soaps were not. A loose acid stool could often be changed to a soap stool by a relative increase in the amount of casein in the food, while an alkaline soap stool could be changed to an acid stool by a relative increase in the amount of carbohydrates. The intestinal flora also changed with the change in the reaction. The absorption of fat in babes that were passing soap stools was less than when the stools were normal. This made one question why so many pediatricians were anxious to get soap stools. Diarrhea, whatever its cause, resulted in an increased loss of fat. The relation between the amount of fat in the food and the absorption of such salts as combined with fat was by no means a simple one. It seemed probable that when there was a large amount of soap the absorption of calcium and magnesium was diminished, and it also seemed reasonable to suppose that

when the fat in the food was increased beyond a certain point there would be an increased loss of mineral salts. This was apparently not the case; data from metabolic experiments showed that in the normal infant a high fat intake did not change the mineral composition of the stools. In chronic malnutrition the output of salts in the feces was considerably raised by increasing the fat in the food, and in these cases there seemed to be a considerable diminution in the absorption of fat. There was nothing in the present knowledge of the digestion and metabolism of fats in infancy to justify the assumption, or even the supposition, that the normal infant could not digest fat in reasonable amounts. It was also evident that the ills that had been attributed to the fat in the food were in reality due to an excess of one of the other food elements or to an improper relation of the food elements to each other. However, in abnormal infants suffering from serious disturbances of nutrition the ability to digest and absorb and utilize fat was unquestionably diminished. Investigation had shown that the infant digested the fat of cow's milk about as well as that of human milk, and thrived on artificial foods containing approximately the same amount of fat as human milk. The caloric value of a gram of fat was 9.3, while that of a gram of starch was 4.1, so that very considerable amounts of carbohydrate must be given to make up for a deficiency of fat, and if the carbohydrates were increased beyond a certain point, carbohydrate indigestion was certain to follow. Fat and carbohydrate could not, therefore, be used interchangeably beyond a certain point. As to just how much fat the infant should take, it might be said, as much as it needed to satisfy its caloric needs, which should be met by fat and not enough to overtax its digestive capacity for fat. Nature had decided that in human milk this was 3.5 to 4 per cent. Dr. Morse said that his experience had taught him that this was the optimum amount after the first few weeks of life for the artificial food of the normal infant. There were many reasons why excessive amounts of fat had been given; among them was the failure to distinguish between normal and abnormal infants. What was proper, advisable, and necessary in the normal infant, was improper, inadvisable, and not only not necessary, but harmful in the abnormal child. It was self-evident that infants that had developed an intolerance for fat could not take without injury the amount of fat which the normal infant needed in order to thrive. It was equally self-evident that when there was an exceedingly acid condition of the intestinal contents the products of the decomposition of fats, which were acid, would increase the symptoms.

Present Opinion as to the Use and Action of Carbohydrates in Infant Feeding.—Dr. THOMAS S. SOUTHWORTH discussed this phase of the subject. After reviewing the part played by the carbohydrates in the human economy, and showing that this was the same in the infant as the adult, he stated that the fact that sugar entered largely into the composition of breast milk indicated that carbohydrates in some form were an essential part of the food of the infant. In the feeding of the normal health infant there really seemed little to choose between the employment of lactose, saccharose, and maltose-dextrin. This statement, however, called for qualifying comments. Lactose would seem to have nature's endorsement. Its lower absorption and favoring influence upon the intestinal flora presented certain advantages, but these might cease upon the occurrence of intestinal disturbances. It might also be mentioned that from the medical standpoint of the production of toxins the sources from which sugar and maltose-dextrin were derived were cleaner than those from which lactose was obtained and that lactose from an unreliable source might be productive of an otherwise inexplicable disturbance of digestion. The relative cost of these three forms of sugar might also be a determining factor among the poor and in certain charitable institutions. It might also be mentioned that the limit of toleration for maltose-dextrin was about double that of the other forms of sugar, and it was less liable to cause disturbance when reasonable amounts were unwittingly exceeded. Probably Finkelstein's most valuable contribution to infant dietetics had been the emphasis which he had placed upon the irritative and laxative effects of the sugars, especially lactose when not well borne and the measures he had suggested for combating them, even though one could not accept his views *in toto*. The injurious effects of carbohydrate intolerance were manifested, when they became irritative in the course of abnormal fermenta-

tion, in increased persistalsis, with its resultant disorganization of the orderly process of absorption in the bowel, and nutritive material was swept out with resulting malnutrition. When this occurred the desideratum was to eliminate or decrease the fermentation in order to restore absorption. The essayist said it was his opinion that this loss of nutritive material from increased persistalsis would in the future play a large part in the management of malnutrition cases. Furthermore, in fat intolerance accompanied by excess of unneutralized fatty acids, or the increased formation of ammonia by the body, an abnormal fermentation of the sugars might intensify the picture. Thus acidosis might be caused not only by the abstraction of alkali but through failure of normal absorption of nutritive material. Here, not only the reduction of the quantity of fat in the food and the administration of some alkali was indicated, but the substitution of a combination of lactose, dextrin, and starch often changed the flora of the intestinal tract and favored much needed absorption. They had long been using cereal decoctions with little regard to the percentages employed, owing to the impression that their action was largely mechanical. But the importance of the careful determination of the percentage of the cereal employed should not be overlooked. It appeared that 0.75 per cent. was within safe limits. The author stated that he had some time ago called attention to the protective, curative, and remedial properties of boiled starch in disturbances of the gastrointestinal tract in infants. Its mechanical value was widely recognized, and that cereal contained vegetable proteins which were utilized would probably also be conceded. Dextrin and starch might be discussed together since they had a close relationship and similar properties. Difference of opinion as to the use of these cereal foods was chiefly confined to the question as to the age at which such utilization became sufficient to be taken into account. Undoubtedly the age varied somewhat with the individual, but as long as amylolytic ferments and their steady increase in production was admitted there was no question of their acting on cooked starch when this was introduced into the food. Such feeding, however, should be kept within safe limits, but in the normal infant these limits were somewhat elastic if the other food elements were well balanced. The essayist discussed the curative and protective action of starch in cases in which there was intestinal disturbance due to faulty digestion of other food elements or to abnormal fermentation or putrefaction of bacterial origin, and showed that there was a definite advantage where the intestinal disturbance had arisen from the use of a single disaccharide, either lactose or saccharose, in substituting for them mixed carbohydrates, dextrin, and maltose, or starches, dextrin, and maltose.

The Parts Played by Salts in Infant Feeding.—Dr. FREDERICK H. BARTLETT read this paper, in which he reviewed the more recent investigations in reference to salt metabolism as they related to the connection between salt, metabolism and the food elements, to the low content of iron in cow's milk as compared with that of woman's milk, to rickets and to gain in weight. In speaking of the relation of salts to proteins, he said that the nitrogen circulating in the blood was loosely held by the tissues, but could not be thus loosely held for any length of time without being excreted unless the salts were in sufficient quantity to make the nitrogen available for the building up of living protein. The investigations of Howland and of Levene, Holt, and Courteney, at the Babies' Hospital, on the effects of high protein feeding and salt metabolism might be summed up by saying that a large intake of protein was accompanied by a large retention of salts, if the intake of salts is also high. The influence of the carbohydrates on salt retention was apparently an indirect one. Carbohydrates increased the water retention, and with the increased water retention there was an increased salt retention. This accounted for the increase in weight sometimes observed in high carbohydrate feeding, but such a gain was by no means to be taken as an index of improved nutrition. The effect of diarrhea on salt metabolism was manifest whatever its cause, since the rapid draining of water from the system interfered with salt retention. After reviewing the work of German investigators with reference to the effect of fat on salt metabolism, the essayist said that in their observations at the Babies' Hospital it was found that there was in the stools which had a high calcium content also a high phosphate content. This would indicate that there was adequate calcium to combine to

form soaps and also to take care of the phosphoric acid. It had also been observed that in infants with soapy stools the calcium loss, as a rule, was not sufficient to cause a negative balance. The molecular weight of the fatty acids was very high, and accordingly only a small weight of calcium was required to hold a relatively large amount of fatty acids. This investigation was not in accord with the conclusions of the German investigators, who regarded the presence of soapy stools as an indication of abnormal digestion involving excessive alkali withdrawal. In the cases observed at the Babies' Hospital it was observed that the only way that fat affected salt metabolism unfavorably was in diarrhea in which was seen a great withdrawal of salts, especially potassium and sodium. Even here this result was largely due to increased peristalsis. It might be said in general that in healthy infants the addition of large amounts of fat to the food disturbed mineral metabolism only to a slight degree. If, however, high fat feedings were persisted in long enough, disturbances might result in which there was a dealkalinization of the tissues of serious import. The practical lesson from these investigations seemed to be to give moderate percentages of fat, such, for example, as were obtained by the dilutions of whole milk. As to the deficiency of iron in cow's milk, as was well known, cow's milk contained much less iron than woman's milk, and when the cow's milk was diluted the iron was reduced to a negligible quantity. It was desirable to make up this loss, for in the author's opinion many children suffered from a failure to supply this deficiency early enough. The deficiency usually manifested itself at the sixth or seventh month, and at this age the loss of iron might be made up by other foods, such as yolk of egg, cereals, green vegetables, and cooked fruit. By giving these articles properly cooked and in small quantities adaptation to them might be brought about without harm. Children thus fed seemed to be stronger and healthier than those exclusively milk fed during the first year. As to the amount of calcium an infant needed if he was to be free from rickets, it had been found that the amount of calcium varied with different children; for instance, a long infant would require more than a short one and a rapidly growing one more than a slowly growing one. An average deposition of 0.17 to 0.18 grams of calcium in the tissues daily was a fair average. It seemed that this question could not be definitely answered, because the cause of rickets seemed to lie in the failure to make use of the calcium which was ingested and not to an inadequate supply in the food. The salts were an essential element in the food in the determination of a gain in weight. A diet without normal salt would invariably be accompanied by a rapid loss in weight, which could only be explained by a loss to the organism of water. The sodium salts were most intimately associated with the retention of water in the organism. The potassium and calcium salts, for the most part had the effect of withdrawing water from the organism. This effect of the salts on the water was only operative if an adequate amount of water was ingested. For an infant of four weeks, each kilogram of body weight required 35 grams of water per kilo body weight. The essayist exhibited charts which showed the results of experiments as to the value of hypodermoclysis in cases in which there had been an excessive withdrawal of water from the tissues. The results of these experiments showed that while hypodermoclysis might produce a temporary retention of salts, say for twenty-four hours, this would be followed by a rapid excretion of salts, so that the procedure was of no permanent value. The question remained, however, whether the retention of salts even for this short period might be of value in cases of severe diarrhea accompanied by a great loss of water.

Dr. CHARLES GILMORE KERLEY expressed himself as having been much impressed by Dr. Bartlett's paper on the salts in cow's milk. This had opened up a field which had been very much neglected. The giving of salts in the form of vegetables when the infant was five or six months of age, as Dr. Bartlett had described, was a point well taken. Of course maternal nursing was the ideal way of feeding a baby, but many babies after reaching the age of seven months showed some signs of malnutrition in the way of rickets if they did not receive additional food. Perhaps a great deal of the credit given to maternal nursing was due to the fact that very frequently where the mother nursed the baby it received additional food at a comparatively early period. Instead of giving egg and milk, especially in young infants, a better scheme was to give protein-free

milk. Dr. Harrison of Yonkers had been preparing a skimmed milk which was protein free and is supplied in powdered form so that one got the salts of the milk and the milk sugar. This preparation could be given in amounts desired to infants on the breast, thus furnishing the amounts of salts that were desirable. This protein-free skimmed milk furnished a useful supplementary feeding. Dr. Morse had spoken of the distinction that must be made between the well child and the sick child. This was a distinction which should always be kept in mind. The well child required and took care of 3 or 4 per cent. of fat, but it was not difficult to feed well babies. Hundreds of them were brought up all over the country on milk and cereal and that was not their problem. It was the feeding of the sick child that taxed all their efforts and in such instances one had to follow a different line of procedure. In case a child had carbohydrate indigestion, one gave it low sugars and found that it would take proteins better. If there was fat indigestion one reduced the amount of fat and made it up by the addition of starch. Some young children had a very good capacity for starch and could tolerate it up to 4 per cent. In these various ways one had to raise the calories to the required amount and thus carry a baby over a difficult feeding period.

Dr. HENRY DWIGHT CHAPIN said he was interested in what Dr. Morse had said with reference to the amount of casein in the feeding being less important than its nature. Many years ago he had called attention to the fact that casein had a developmental function in young animals and in infants as well as a nutritive function. The protein in the milk of different animals coagulated in different ways. In the ruminant herbivora the casein coagulated in hard lumps which were intended to develop the motility of the animal's stomach, because the animal must later feed on grass, grain, etc. In this class of animals the stomach was 70 per cent. of the entire digestive tract, and it was of importance that the casein be of such a character as would develop the motility of this organ. On the other hand in the non-ruminant herbivora, the mare and the ass, the casein coagulated in a gelatinous mass, that passed easily through the pylorus, and later on digestion was largely in the intestines in these animals. In human milk, which was midway between these two, the coagula was soft and flocculent. In the infant the stomach was only 20 per cent. of the digestive tract, so that a considerable portion of the digestive process took place in the intestines. Thus they learned from biology that the casein had not only a nutritive but also a developmental function to perform, and they had learned why they need not be as much afraid of giving protein as they formerly were, and why it was not advisable to go to extremes in trying to modify it. At birth the different species of animals all digested milk alike, but at the end of a year all were taking different kinds of food. The milk had developed the digestive tract in each species in a different way, and if one wished to be successful in feeding infants he would have to follow nature. Dr. Chapin said he was glad to hear Dr. Morse champion fats as he did. We had frequently been giving too low fats and placing too much emphasis on calories. One could get the required number of calories by substituting starch for fat, but there was danger in this method that rickets would result.

Dr. MORRIS STARK called attention to the work of Funk with reference to beriberi and pellagra. He had shown that these were probably deficiency diseases due to the lack of certain substances in certain carbohydrate foods, in rice in the case of beriberi and in maize in reference to pellagra. These substances Funk had called vitamins, and they were absolutely necessary if certain carbohydrates were to fulfill their nutritive function. It was possible that these vitamins might have a definite relation to rickets, which was probably also a deficiency disease. If a study was made of metabolism in rickets and these other deficiency diseases we might get much more definite knowledge on this subject.

PHILADELPHIA NEUROLOGICAL SOCIETY.

At a stated meeting held March 24 Drs. CHARLES W. BURR and WILLIAMS B. CADWALADER presented a "Report of a Case of Pellagra in a Child, with Necropsy." The patient was a child, eleven years old, of Italian parentage, but born in the United States, who presented an appearance of imbecility, but who was found on ex-

amination to possess average intelligence. She presented a spastic-ataxic-paralytic gait, with exaggerated reflexes, but no appreciable muscular wasting, and no sensory changes. There was an erythematous eruption on face and hands. Wassermann and tuberculin tests yielded negative reactions. While under observation an attack of diphtheria developed without complications, and at a later date death resulted. Post-mortem examination disclosed no gross lesion, but on histological examination degenerative changes were found in the ganglion cells of the spinal cord and in the nerve-fibers of the anterolateral and posterior columns.

Dr. WILLIAM E. DRAYTON presented "A Case of Pellagra," occurring in a child of American parentage who had never been out of the country, and who had never partaken of cornmeal in any form. In addition to a more or less persistent diarrhea the child exhibited a spastic-ataxic gait, with exaggeration of the reflexes and for a time a batwing erythema of the face. Negative reactions were obtained to Wassermann and Moro tests, and the blood exhibited evidences of secondary anemia. The cutaneous exanthem disappeared under observation, but the peculiar gait and the exaggeration of reflexes persisted.

Dr. ALFRED GORDON exhibited "A Case of Progressive Muscular Atrophy of the Scapulo-Humeral Type." The patient was a woman of about twenty-four, who for several years had noticed weakness in the upper extremities more especially on the right side, with muscular wasting without fibrillary twitching and with alar scapulæ. The reflexes were diminished in the upper extremities, but not altered in the lower, and the muscular responses to electric stimulation also were diminished. The calves of the legs were not enlarged. The Wassermann reaction yielded a negative response. The condition was looked upon as a dystrophy of progressive type.

Dr. NATHAN S. YAWGER demonstrated "A Condition in the Hand Resembling Raynaud's Disease Resulting from Frost-Bite." The patient was a brakeman about twenty-five years old, who, following exposure to severe cold, found the right hand swollen and painful and thereafter, particularly in cold weather, the affected member would become white, especially when elevated, and be the seat of burning and cutting pain. From time to time ulcers formed on the fingers and healed. No other part of the body was affected.

Dr. FRANCIS X. DERCUM exhibited "A Case of Tumor Giving Rise to Brachial Plexus and Sympathetic Palsies (Klumpke-Dejerine Symptom-group)." The patient was a young man twenty-three years old, engaged in the manipulation of a waterhammer, and in whom weakness developed in the right upper extremity, together with the appearance of retraction of the eyeball on the right side, narrowing of the palpebral fissure and contraction of the pupil. Examination disclosed a neoplastic mass in the right supraclavicular region and in the upper portion of the anterior aspect of the right chest. Under treatment with Coley's fluid and x-ray applications improvement ensued, with noticeable reduction in the size of the growth.

Dr. DERCUM also demonstrated "A Case of Probable Disease of the Pineal Gland." The patient was a man, twenty-eight years old, of rather diminutive stature, without hair on the face and in the axilla and but slight growth on the pubes. For a number of months there had been headache and vomiting, and examination of the eyegrounds disclosed optic atrophy consecutive to neuritis. Carbohydrate tolerance was unaltered and there was no change in the size of the bones of the skeleton; nor could any change in the size of the thymus be demonstrated. X-ray examination disclosed a condition of internal hydrocephalus, with atrophy of a portion of the sphenoid bone.

Dr. S. F. GILPIN exhibited "A Case of Paralysis Agitans (?) with Unusual Symptoms." The patient was a man, about fifty years old, who had been a stationary fireman, and who presented synchronous tremor of the right hand and of the head, with rather a fixed countenance and some awkwardness of speech. There was also immobility of the pupils, which were somewhat dilated, and also paroxysmal cough of a suffocative character, without intralaryngeal abnormality except for some displacement of the epiglottis. The tongue when protruded was slightly deflected to the left and the left side of the face appeared rather more active than the right.

Dr. SAMUEL LEOPOLD reported "A Case of Jacksonian Epilepsy limited to the Right Upper Extremity." The patient was a young man who had received an electric

shock of high voltage, and who subsequently on numerous occasions exhibited tonic flexion of the right arm on the forearm, with application of the right upper extremity against the chest-wall. Only on one or two occasions was there loss of consciousness or biting of the tongue, and there was no loss of control of sphincters in the attacks. There was no palsy and no changes in the eyegrounds.

Dr. E. M. AUER read a communication (see page 641), entitled "Phenomena Resulting from Fatigue and Shock of the Central Nervous System Observed in France."

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OKLAHOMA STATE BOARD OF MEDICAL EXAMINERS.

January 11 and 12, 1916.

ANATOMY.

1. Give terminal branches of external carotid artery.
2. Describe popliteal space, giving boundaries, contents, and relations.
3. Name structures seen in cross section at middle of forearm.
4. Give anatomy of appendix with reference to its being a cause of appendicitis.
5. Give origin, relations, and branches of phrenic nerve.
6. Describe the "circle of Willis." What is its anatomical purpose?
7. Give anatomical reasons for varicocele occurring more frequently on left side.
8. Give weight of human brain; of the liver. Name lobes of the liver.
9. From what blastodermic layer are the following derived: Skin, intestinal tract, brain, spinal cord?
10. Make cross section of coverings of skull, including five layers.

CHEMISTRY.

1. Name the halogen group and give physical property of each.
2. What is the specific gravity of normal urine? Diabetic?
3. Give chemical formula of nitric acid; of silver nitrate; barium chloride; common salt; ferrous chloride.
4. What are your chemical tests for cancer of the stomach?
5. Define difference between -ic and -ous salts.
6. Define molecule, atom, chemical affinity, an acid, an alkali, and a salt.
7. What is chemistry? Organic chemistry? Inorganic chemistry?
8. Give two tests for albumin.
9. What is Fehling's solution? Haines'? What is aspirin?
10. What is your antidote for carbolic poisoning? For lye poisoning?

MATERIA MEDICA.

1. Write a prescription demonstrating what is meant by chemical incompatibility; give reasons.
2. What is meant by emmenagogue? Name three with their dosage.
3. Name the hypnotic drugs; give dose of each.
4. Name two general anesthetics and the signs indicative of danger to the patient in the administration of each.
5. What is the official name for calomel? Give dose. With what class or classes of drugs is it incompatible and why?

BACTERIOLOGY.

1. Define aerobic and anaerobic bacteria. Give an example of each variety.
2. How would you prepare a specimen of blood for examination in which malarial plasmodium was suspected?
3. Describe and give method of staining *Bacillus diphtheriae*.
4. Name six systemic diseases caused by microorganisms; name and describe each microorganism.
5. What microorganism may cause meningitis? Where is it located and what is the appearance of the microorganism causing epidemic meningitis?

PATHOLOGY.

1. What changes occur in the tissues of the body after death?

2. Describe hypertrophy and atrophy; give example of each process.
3. Give pathological and clinical causes of edema.
4. Define leucocytosis; name varieties and give significance of each.
5. Give the pathology of pneumonia, pleurisy, influenza, acute parenchymatous nephritis.

PHYSICAL DIAGNOSIS.

1. Name the types of dyspnea.
2. Give technique for percussing the thorax.
3. Describe lung reflex and give causes.
4. Diagnose gallstone.
5. Name physical signs of aneurysm of the abdominal aorta.
6. Diagnose pulmonary stenosis.
7. Name the anomalies of respiration.
8. Name the topographic lines and areas of the thorax.
9. Describe the typical phthisical chest.
10. Differentiate gastric ulcer from cancer.

PRACTICE.

1. Outline the treatment of cirrhosis of the liver.
2. Differentiate between cholera infantum and cholera morbus; give ordinary treatment of each.
3. Give etiology, symptoms, and treatment of pertussis.
4. Describe the Wassermann reaction. What is its significance and value?
5. Define rubeola and describe its symptoms.

ANSWERS.

ANATOMY.

1. The terminal branches of the external carotid artery are the superficial temporal and the internal maxillary arteries.

2. THE POPLITEAL SPACE is bounded: *Above, and externally by the Biceps; above, and internally by the Semimembranosus and Semitendinosus; below, and externally by the Plantaris and external head of the Gastrocnemius; below, and internally by the inner head of the Gastrocnemius.* Contents: Popliteal vessels with branches, external saphenous vein, external and internal popliteal nerves, small sciatic nerve, lymphatic glands, and loose areolar tissue.

The internal popliteal nerve is superficial, and lies in the middle line of the space; it crosses the artery from without inward. The external popliteal nerve is close to the tendon of the biceps. The popliteal vein is superficial to the popliteal artery; it is at first on the outer side of the artery, and then to the inner side. The lymphatic glands are found surrounding the artery.

3. In amputation of forearm at middle third there will be severed: Skin, fascia, supinator longus, extensor carpi radialis longior and brevior, extensor communis digitorum, extensor carpi ulnaris, supinator brevis, anconeus, pronator radii teres, flexor carpi radialis, palmaris longus, flexor sublimis digitorum, flexor carpi ulnaris, flexor profundus digitorum; arteries: anterior interosseous, radial, ulnar; veins: radial, interosseous, ulnar, median; nerves: posterior interosseous, radial, median, ulnar; bones: radius, ulna.

4. The *vermiform appendix* is a long, narrow, musculomembranous tube which is given off, as a rule, from the inner side of the posterior wall of the cecum; but its position, as well as its size and direction, are very variable, usually it is about 2 or 3 inches in length by about $\frac{1}{8}$ to $\frac{1}{4}$ inch in diameter, but it may vary in length from $\frac{1}{2}$ to 9 inches. It generally points upward and inward (in a line pointing toward the spleen); it may be found in almost any relation to the cecum and ascending colon. It consists of four coats: the serous (usually completely covering the appendix, and making a mesentery), the muscular, submucous, and mucous; this last contains bloodvessels, nerves, and lymphatic glands.

The features which make it particularly liable to infection, are: It is a long, narrow, tube, blind at one extremity, containing a large amount of lymphoid tissue of low vital resistance and therefore very prone to bacterial infection; the blood supply is defective, the appendicular artery having (as a rule) no anastomosis, and only traveling part of the length of the appendix; any twist or obstruction here means gangrene; further, drainage is deficient, owing to its position. The meso-appendix may be too short, and so cause twisting or curling, with resultant obstruction.

5. The *phrenic nerve* is derived from the third, fourth,

and fifth cervical nerves; it lies in front of scalenus anticus, descends inward on it in front of subclavian artery to enter the chest, having crossed the internal mammary artery at origin, behind the subclavian vein. In the thorax it descends in front of the root of the lung, being between the pericardium and the mediastinal pleura, to the diaphragm, which it perforates, and is distributed on its abdominal surface. The *right* nerve lies outside right innominate vein and superior vena cava. The *left* nerve in the neck is crossed by the thoracic duct, and below crosses the arch of the aorta and left pneumogastric, and is longer than the right. Filaments from each supply the pericardium and pleura. *Deep branches*, are: *Communicating*: to spinal accessory in sternomastoid and trapezius muscles. *Muscular*: to sternomastoid, levator anguli scapulae, scalenus, and trapezius. (*Aids to Anatomy.*)

6. The circle of Willis is situated at the base of the brain. The *circle of Willis* is formed: In front by the two anterior cerebral arteries (branches of the internal carotid) which are connected by the anterior communicating artery; behind, by the two posterior cerebrials (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.

The circle of Willis equalizes the flow of blood in the brain, and tends to preserve the cerebral circulation when one or more of the branches of the supplying arteries are obliterated.

7. *Varicocele* occurs more frequently on the left side, on account of the greater pressure in the left spermatic vein (which enters the left renal vein at a right angle, and not like the right vein which enters the inferior vena cava at an acute angle); also, on account of the greater length of the left spermatic vein, the left testicle being lower than the right one; and the left spermatic vein is more exposed to pressure (from the sigmoid colon).

8. The average weight of the human brain is a little less than 50 ounces (about 45 to 50 ounces); the liver weighs about 50 ounces (50 to 60 ounces in the male, and 40 to 50 ounces in the female).

The lobes of the liver, are: Right, left, quadrate, spigelian, and caudate.

9. The skin is derived from the ectoderm; the *intestinal tract*, from entoderm; *brain and spinal cord*, from the ectoderm.

10. The *coverings of the skull*, are, from without inward: (1) Skin; (2) Superficial fascia, with fatty tissue and arteries and nerves; (4) Muscular fibers and the aponeurosis of the occipito-frontalis; (4) loose cellular tissue, called the "dangerous area"; (5) the pericranium.

CHEMISTRY.

1. The *halogen group* consists of: Fluorine, chlorine, bromine, and iodine.

Fluorine is a gas, with a very faint greenish-yellow color; it becomes a liquid at a temperature of -187° C.; it decomposes water; it is very irritant to mucous membranes.

Chlorine is a greenish-yellow gas, with a penetrating odor; it is soluble in water; it is very irritant to mucous membranes.

Bromine is a dark, reddish-brown liquid, volatile, and giving off irritating fumes; it is slightly soluble in water, more soluble in alcohol, chloroform, and ether; it boils at 59° C., and becomes solid at -7° C.

Iodine is a solid, occurring as blue-gray crystalline scales; it is volatile, and its vapor is of a violet color; it is very slightly soluble in water, but is soluble in alcohol, chloroform, and ether.

2. The specific gravity of normal urine is about 1015 to 1025; of diabetic urine, about 1030 to 1050.

3. Nitric acid, HNO₃; silver nitrate, AgNO₃; barium chloride, BaCl₂; common salt, NaCl; ferrous chloride, FeCl₂.

4. Chemical tests for cancer of the stomach, are absence of free hydrochloric acid, and presence of lactic acid in the stomach contents after a Boas' test-breakfast.

5. When two salts contain the same two elements, the salt containing the less proportionate quantity of the more electronegative element, terminates in *-ous*; the salt containing the greater proportion of the more electronegative element ends in *-ic*. Thus SO₂, sulphurous oxide; SO₃, sulphuric oxide. Hg₂Cl₂: mercurous chloride; HgCl₂, mercuric chloride.

6. A *molecule* is the smallest portion of a substance (element or compound) which can exist free.

An *atom* is the smallest quantity of an element which can enter into the composition of a molecule.

Chemical affinity is the force which attracts atoms to each other.

An *acid* is a compound of an electronegative element or residue with hydrogen, which hydrogen it can part with (in whole or part) in exchange for an electropositive element, without the formation of a base.

An *alkali* is a substance which is strongly basic, of an alkaline reaction, and capable of saponifying fats.

A *salt* is a substance formed by substituting part or all of the replaceable hydrogen of an acid by an electropositive element.

7. *Chemistry* is that branch of science which deals with the composition of bodies, their changes in composition, and the laws governing such changes.

Organic chemistry is the chemistry of the carbon compounds.

Inorganic chemistry is the chemistry of such substances as do not contain carbon.

8. *Two reliable tests for albumin in the urine*: "The urine must be perfectly clear. If not so, it is to be filtered, and if this does not render it transparent, it is to be treated with a few drops of magnesia mixture and again filtered."

I.—*The heat test*: "The reaction is first observed. If it be acid, the urine is simply heated to near the boiling point. If the urine be neutral or alkaline, it is rendered faintly acid by the addition of dilute acetic acid, and heated. If albumin be present, a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3 ."

II.—*Heller's modification of the nitric acid test*: "Place in a test-tube a layer of HNO_3 about 2 c.c. in thickness; then, with a pipette, carefully float upon the surface of this a layer of the urine in such a manner that the liquids do not mix. If albumin be present, a cloudy ring appears at the point of juncture of the two layers, the borders of the cloud being sharply defined. A cloudy ring may be formed by the presence of an excess of urates, but in this case it is not at, but above, the point of junction of the layers, and its upper border is not sharply defined, but fades off gradually."—(Witt-haus' *Essentials of Chemistry*.)

9. *Fehling's Solution*: The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gr. of crystallized CuSO_4 , dissolved in water to 500 c.c.; and Solution II of 130 gr. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.

Haines' Solution: Dissolve 30 grains of copper sulphate in half an ounce of distilled water, and add half an ounce of glycerin; mix thoroughly, and add 5 ounces of liquor potassæ.

Aspirin is acetyl salicylic acid, $\text{C}_6\text{H}_5\text{O.COCH}_3\text{COOH}$.

10. *Antidote for carbolic acid poisoning*: Sodium sulphate, in solution; alcohol.

Antidote for lye poisoning: Vinegar, or a weak acid, followed by oil or milk.

MATERIA MEDICA.

1. R
Ammonii carbonatis 5j.
Syrupi Tolutani.
Syrupi Scillæ aa 5iv.
Aquæ p. s. ad. 5vj.M.

Sig. Take half an ounce every four hours.

In this prescription, the syrup of squill contains free acetic acid, and this acting on the ammonium carbonate produces effervescence and forms ammonium acetate. If the prescriber intended this, the prescription is not considered incompatible.

2. *Emmenagogues* are agents which restore the menstrual function. As: Wine of ergot, 3ij; Apiol, gr. xij; Potassium permanganate, gr. ij.

3. *Hypnotics*: Sulphonal, gr. xv; trional, gr. xv; tetronal, gr. xv; veronal, gr. viij; paraldehyde, ℥xxx; chloral hydrate, gr. xv; urethane, gr. xv; medinal gr. xv; chloral formamide, gr. xv; chloralose, gr. iv.

4. Ether and Chloroform.

Signs indicative of danger in the administration of ether: Pupils widely dilated and immobile; complexion pale and dusky; respiration shallow, jerky, and irregular.

Danger signs in chloroform anesthesia: Respirations becoming irregular or ceasing; pulse feeble, irregular,

or imperceptible; pupils widely dilated and not reacting to light; complexion dusky or very pale.

5. The official name of calomel is Hydrargyri Chloridum mite; laxative dose is gr. ij; alterative dose gr. j.

Incompatibles of Calomel: Solutions of alkalies and their carbonates convert calomel into a black mass, usually the black oxide; ammonium hydroxide and carbonate form with it a complex black compound. Iodides, bromides, cyanides, and other reducing agents convert it into mercury and a mercuric compound. Oxidizing agents oxidize it to the mercuric state. Exposure to sunlight gradually decomposes it; the process is accelerated by the presence of iodoform and other organic substances. (Marshall's *Manual of Prescribing*.)

BACTERIOLOGY.

1. *Aerobic bacteria* are such as require the presence of oxygen in order to live and grow, as the bacillus of influenza. *Anaerobic bacteria* are such as can only live and grow in the absence of oxygen, as the tetanus bacillus.

2. *Method of preparing blood for examination for malarial plasmodia*: "This consists in spreading a very thick layer of blood, drying, placing for a few minutes in a fluid containing 5 per cent. formalin and 1 per cent. acetic acid, which removes the hemoglobin and fixes the smear, rinsing, drying, and finally staining. Carbol-thionin is very useful for this purpose. If Wright's stain be used in this method, it is recommended that the preparation be subsequently stained for a half minute with borax-methylene-blue (borax, 5; methylene-blue, 2; water, 100)." (Todd's *Clinical Diagnosis*.)

3. *The characteristics of the bacillus of diphtheria*: The bacilli are from 2 to 6 mikrons in length and from 0.2 to 1.0 mikron in breadth; are slightly curved, and often have clubbed and rounded ends; occur either singly or in pairs, or in irregular groups, but do not form chains; they have no flagella, are non-motile and aerobic; they are noted for their pleomorphism; they do not stain uniformly, but stain well by Gram's method and very beautifully with Loeffler's alkaline-methylene-blue.

4. *Six diseases caused by microorganisms*: Typhoid, malaria, pneumonia, gonorrhea, syphilis, anthrax.

Typhoid fever is caused by the *Bacillus typhosus* of Eberth. This organism is rod-shaped, with rounded ends, is from 2 to 4 microns in length, and about three-fourths of a micron in breadth; it does not stain by Gram's method, but stains with all the anilin dyes; it has flagella, no spores, is aerobic and facultative anaerobic, and is motile.

Tuberculosis is caused by the *Bacillus tuberculosis*. This is a small, slender rod, slightly curved, occurring singly or in chains; it is 3 or 4 microns long, and about 0.2 to 0.4 micron broad. It is non-motile, does not form spores, is aerobic, and stains with difficulty.

Pneumonia is caused by the *diplococcus pneumoniae* (of Fraenkel). This is a coccus, occurring in pairs, it has a capsule, is non-motile, stains readily with anilin dyes and by Gram's method; it is aerobic and facultative anaerobic.

Gonorrhea is caused by the *gonococcus*, which is a diplococcus with the appearance like that of two coffee beans; it is aerobic, can be cultivated on human blood serum; will not grow on gelatin, agar, bouillon or potato; it stains with ordinary anilin dyes but not by Gram's method.

Syphilis is caused by the *treponema pallidum*, which is a slender spirillum with regular turns, about 4 to 20 mikrons long, with a fine flagellum at each pole; it is flexible, hard to stain, and has not been cultivated on artificial media. How it divides is not known. It stains best with Giemsa's eosin solution and azur.

Anthrax is caused by the *Bacillus anthracis*, which is a large, rod-shaped microorganism with slightly thickened ends; it is from 5 to 20 mikrons in length, and a little more than one mikron in breadth; it has a tendency to form long threads, is non-motile, non-flagellated, and aerobic; it stains by anilin dyes and also by Gram's method.

5. *Meningitis* is caused by the *diplococcus intracellularis meningitidis*, also by the tubercle bacillus, and the diplococcus of pneumonia.

The *diplococcus intracellularis meningitidis* occurs in the polynuclear leucocytes of the exudate, and may be obtained from the cerebrospinal fluid and the nasal secretion. It resembles the gonococcus, but may appear within or outside the cells; the size is variable; it grows readily on meat infusions, and is probably Gram negative; it is aerobic.

PATHOLOGY.

1. After death, the temperature of the body falls to that of the surrounding atmosphere; the dependent parts of the body become discolored; rigor mortis, or a stiffening of the muscles appears (this is due to the coagulation of the albumin of the muscles, with the formation of myosin); the cornea loses its transparency, the tissues lose their elasticity, the pupils dilate, the sphincters relax; the body becomes discolored, the tissues soften, an odor is given off, and decomposition takes place.

2. *Hypertrophy* is an increase in the size, weight, and functional activity of a part beyond the limit of health, due to an orderly enlargement or multiplication of all its normal constituents. Its nature is physiological; it is pathological only in extent. Hypertrophy is said to be compensatory when one organ carries on the work formerly accomplished by two organs. The uterus and the mammary glands hypertrophy during pregnancy.

Atrophy is a decrease in the amount of a tissue owing to a diminution either in size (simple atrophy) or in number (numerical atrophy) of the histological elements of which it is composed. Loss of weight and impairment of function are generally observed. It may be general or local. *Example:* Atrophy of the sexual organs in old age.

3. *Causes of edema:* "Six factors enter into the production of edema, usually more than one acting at a time, *viz.* positive pressure in the vessels, permeability of the vessel walls, osmosis from excess of salts outside the vessel, selective action of the endothelium, variations in the blood plasma, and obstructed onflow in the lymph channels." (Thayer's *Pathology*.)

4. "*Leucocytosis* is that condition of the blood in which the leucocytes are temporarily or persistently increased in number. When several forms of leucocytes are increased in number and the usual proportions are but partially disturbed, we speak of *mixed leucocytosis*. Such a condition is seen in some forms of anemia. When the polynuclear neutrophile leucocytes alone are increased, the condition is termed *polynuclear leucocytosis*, or simply *leucocytosis*. If the mononuclear cells are chiefly affected, the condition may be denoted as *lymphocytosis*. The eosinophile cells alone may be increased. *Polynuclear leucocytosis* may be either *physiological* or *pathological*. The *physiological* is seen during normal digestion, in the later months of pregnancy, and in the first days of infancy, and is usually of moderate grade. The *pathological* variety occurs in many inflammatory and infectious diseases, and accompanies the various cachexias. Of the infectious diseases attended with leucocytosis may be mentioned pneumonia, diphtheria, scarlet fever, erysipelas, rheumatism, suppurative cerebrospinal meningitis, and any disease associated with a pronounced exudative or suppurative lesion." (Delafield and Prudden's *Pathology*.)

5. **ACUTE LOBAR PNEUMONIA:** "It is convenient to describe four stages, those, namely, of (1) hyperemia or engorgement, (2) red hepatization, (3) gray hepatization, and (4) resolution. *First stage or splenization.*—The lung is injected, dark red, and heavy, and pits under the finger; on pressure, there exudes a frothy serum tinged with blood and slightly aerated. The lung still floats in water. *Second stage or red hepatization.*—The part involved in solid and friable, presents a granular or red granite appearance, and sinks in water. The alveoli are filled with a coagulated exudation which shows under the microscope fibrin, leucocytes, red corpuscles, proliferated alveolar epithelium, and pneumococci. *Third stage or gray hepatization.*—The lobe has now the appearance of gray granite, the lung substance is softer and more friable; on pressure, a dirty purulent fluid exudes. The gray appearance is due to four factors: (1) Decolorization of the red blood corpuscles; (2) obliteration of the alveolar blood vessels from pressure; (3) fatty degeneration of the coagulated material; (4) great infiltration of leucocytes. A more advanced stage, in which the lung tissue is bathed in purulent fluid, is known as purulent infiltration. It is probably inconsistent with life. *Fourth stage or resolution.*—Resolution of the inflammatory exudation is brought about principally by absorption (autolysis), but partly by liquefaction and expectoration. Pneumonia may affect a lobe, or the whole of a lung, or it may attack both lungs. Double pneumonia occurs in about 10 per cent. of cases. Different parts of the same lung may at the same time show different stages. There is always some degree of pleural inflammation over the affected area. Moderate

enlargement of the spleen is very common." (Wheeler and Jack's *Practice of Medicine*).

Acute pleurisy: "As in inflammation of other serous membranes there are five stages—hyperemia, exudation, effusion, absorption, and adhesions. The first stage is marked by congestion and irregularly diffused redness of the membrane with scattered flakes of exudation. The second stage is characterized by the copious formation of lymph, which more or less completely covers the membrane, giving it a dull, cloudy, or shaggy appearance. If the inflammation ceases at this point, it is termed dry pleurisy. If the condition progresses, an effusion is poured out into the pleural cavity, which may be serofibrinous, fibrinous, or purulent. The serofibrinous variety is most frequent and consists of a straw colored fluid containing fibrinous flocculi, blood, and epithelial cells. Its quantity is usually rather large. When the exudate is fibrinous, the amount is small and the consistency is greater than that of the preceding. It undergoes organization quickly and gives rise to adhesions and pleural thickening. The exudate becomes purulent (empyema) only as the result of microorganismal infection. The effusion may become bloody in some instances as the result of ulceration (tuberculous or cancerous) and grave blood diseases. Displacement of the viscera is common in this stage; if on the right side, the effusion pushes the heart farther to the left; if on the left side, the heart is displaced to the right, the impulse often being seen to the right of the sternum. The lungs are also compressed and displaced upward and against the spinal column. On removal of the fluid they again expand, except in cases of chronic pleurisy, in which the adhesions interfere with the functional activity of the pulmonary structure. Absorption of the effused material is the natural sequence in most cases. Unabsorbed portions undergo organization, producing adhesions, which, in extreme instances may obliterate the entire pleural cavity. Sacculization of the effusion by adhesions is not uncommon, especially in purulent exudations in which the adhesions form an abscess wall. Varying degrees of adhesions of the opposing pleural surfaces are encountered, depending on the character of the exudate." (Hughes' *Practice of Medicine*.)

Influenza: There are no characteristic lesions; a catarrhal inflammation of the respiratory tract may be found, and occasionally enlargement of the spleen and the lymph follicles in the small intestine.

Acute parenchymatous nephritis: "The kidneys are usually enlarged, soft, and edematous, the cortex pale and the stellate veins injected. The capsule strips easily, although tense, and the kidney may bulge through the incision. On section, bloody fluid escapes. The cortex is thicker than normal and is much paler than the medulla, which is dark red. The glomeruli may appear as minute red dots. The anemia of the cortex is due to the swelling of the cells, which compress the capillaries. The epithelium is swollen, cloudy, and in many places has become desquamated. This is most marked in the convoluted tubules." (McConnell's *Pathology*.)

PHYSICAL DIAGNOSIS.

1. *Types of dyspnea:* Inspiratory, expiratory, constant paroxysmal, that which occurs only on exertion, and a simple accelerated respiration.

2. *Percussion:* "The pleximeter finger having been laid firmly and smoothly upon the surface to be percussed and adapted to its inequalities, the stroke is delivered upon the middle phalanx of the finger by the plessor finger, its tip striking vertically upon the pleximeter finger. The blow should be given by a quick, elastic movement of the wrist and finger joints, the hammer-finger rebounding at once in order not to damp the vibrations which have been initiated. It is sometimes serviceable to place the four fingers of the left hand upon the surface and percuss from one to the other with successive single strokes. A change from dulness to resonance is often thus brought out with unusual clearness." (Butler's *Diagnostics of Internal Medicine*.)

3. *Lung reflex:* If a spray of ether is directed over the borders of the lungs posteriorly, the lung borders will descend from 2 to 4 inches. The application of any cutaneous irritant or stimulus over any point in the course of the distribution of the pneumogastric nerve will cause a dilatation of the lungs.

4. In *gallstones*, while the calculus remains free in the gall-bladder, usually there are no symptoms. Impaction of the stone in the common duct gives rise to intermittent jaundice, following sharp pain in the right

hypochondriac or epigastric region, frequently radiating toward the right scapula, nausea, vomiting, sweating, depression, and often intermittent fever (Charcot's intermittent fever). When the stone is impacted in the cystic duct, jaundice is less common, but the hepatic colic is severe, and dropsy of the gall-bladder may occur. The diagnostic points are the age, and history of previous attack, with jaundice and intermittent fever, location of the pain, dark, amber-colored urine, containing bile, and sometimes the finding of the stone in the feces.

5. *Aneurysm of the abdominal aorta*: The physical signs are abnormal dullness over a large area to the left of the median line and near the left lobe of the liver, a tumor with expansile pulsation (generally in the epigastric region; a systolic bruit may be heard over the swelling; and sometimes there is a soft diastolic murmur. The femoral pulse is apt to be small and delayed.

6. In *pulmonary stenosis*, a systolic murmur is heard in the second left intercostal space; this murmur is not transmitted, but a systolic thrill is heard over the precordium. The right ventricle is enlarged. The pulmonary second sound is weak. Murmurs of hemic origin are to be excluded.

7. *Anomalies of respiration*: Respiration may be exaggerated, puerile, feeble, emphysematous, asthmatic, cavernous, amphoric, bronchovesicular, or tubular; egophony, bronchophony, and pectoriloquy; vocal resonance may be increased, diminished or absent; râles and friction sounds may be present.

8. The *lines of the thorax*, are: Midsternal, sternal, parasternal, mammary, anterior axillary, midaxillary, posterior axillary, scapular, midspinal (all of which are vertical); and the following horizontal lines: From cricoid cartilage to outer end of clavicle, through third chondrosternal articulation, through sixth chondrosternal articulation, the line of the clavicles, through the spines of the scapulæ, through the inferior angles of the scapulæ.

The *regions of the thorax*, are: (1) Anterior region, containing the clavicular, supraclavicular, infraclavicular, mammary, inframammary, and upper and lower sternal regions; (2) Posterior region, containing the scapular, suprascapular, infrascapular and interscapular regions; and (3) Lateral regions, containing the axillary and infra-axillary regions.

9. The *phthisical chest* is characterized by a short anteroposterior diameter and a long vertical diameter. The chest is flat, and the ribs are oblique. The supraclavicular and infraclavicular spaces are much depressed, and an acute angle is formed at the lower portion by the divergence of the costal margins from the sternum. Posteriorly the scapulæ are very prominent. (Hughes' *Practice of Medicine*.)

10. *Carcinoma of the stomach* does not usually occur before forty years of age, is more common in males, the pain is localized and constant, vomiting is copious and occurs some time after eating; the vomitus contains "coffee ground" material; hemorrhages are common; a tumor may be palpated, and examination of the gastric contents shows absence of free HCl and presence of lactic acid; severe anemia and cachexia are also present.

Ulcer of the stomach is generally caused by injury or bacteria, is most apt to occur between the ages of twenty and forty-five; after eating there is pain localized in the stomach, vomiting occurs soon after eating, hematemesis is common, there is localized tenderness over the stomach, and examination of the gastric contents shows an excess of free HCl.

PRACTICE.

1. *Treatment of cirrhosis of the liver*: "The diet should be restricted to milk and similar unirritating food. Fatty and saccharine substances should be eliminated. Alcoholic individuals should be advised to cease drinking. The gastrointestinal catarrh should receive symptomatic treatment. Bichloride of mercury, sodium phosphate, and potassium iodide are highly recommended. The portal congestion is best relieved by salines. The abdominal dropsy or ascites will require the administration of saline purgatives and diuretics. A half ounce of a concentrated solution of magnesium sulphate taken daily before breakfast is of value, as is also the pill containing 1 gr. each of calomel, digitalis, and squill when given after each meal. Acetate of potassium may also be used. Tapping is necessary when these measures fail.

"*Surgical treatment*, with a view to establishing an anastomosis between the portal and systemic circula-

tion, has been employed; but it should never be considered in the presence of complicating renal or cardiac disease." (Hughes' *Practice of Medicine*.)

2. *CHOLERA INFANTUM*: "*Symptoms*.—Diarrhea is the initial symptom. The stools are more or less fecal, but soon become watery, colorless, and odorless. In some cases they may be of a brownish-green color with a musty odor. There are restlessness, high fever (105-108° F.), thirst, vomiting, and purging. The child rapidly wastes, and the surface temperature falls. The urine is scanty or suppressed, and the child becomes apathetic, which condition may pass on to convulsions, stupor, and death.

"*Treatment*.—Ordinary diarrhea should be prevented from terminating in cholera infantum. The stomach and colon should be irrigated. From 3-4 of water at 100° F. should be allowed to flow into the stomach through a soft-rubber catheter and be siphoned out. This should be done only once. For the colon, sodium bicarbonate, 3 1, should be added to the pint and the irrigation performed twice daily. If the rectal temperature is very high, ice-cold water should be used; otherwise warm water. When symptoms of collapse appear, hot pack is used. Ice water quenches the thirst, even if it is vomited. Champagne and drop-doses of brandy may be given if the stomach is tolerant. Strychnine, gr. 1/100-1/48, hypodermically, to a child one year old, is a valuable stimulant. Morphine, gr. 1/100, and atropin, gr. 1/800, may be given in the same way and repeated every hour until the child is quieted. If the child's condition improves, food must be administered with the utmost caution; bland liquids only should be used."

CHOLERA MORBUS: "*Symptoms*.—The onset is generally at night or in the early morning hours. Nausea, vomiting, and purging of a bilious material, severe colicky pains in the abdomen, moderate fever, and prostration are present. Profuse liquid diarrhea then ensues and considerable tenesmus is present. The pulse is rapid and feeble, and there is intense thirst. Cholera morbus is distinguished from Asiatic cholera and poisoning by arsenic, mercury, and antimony by the time of onset, by the sour and bitter taste of the vomit, free from blood, the colicky pain in the abdomen, the absence of blood in the stools, the absence of metallic substances in the vomit and feces, the history and absence of the comma bacillus in the stools.

"*Treatment*.—Hot turpentine stupes to the abdomen or morphine, gr. 1/4, hypodermically may be given for the pain. Salines should be administered to remove the offending particles. Should the salts move the bowels too frequently, give paregoric, 3 1, and compound tincture of lavender, 3 1, every three hours until two or three doses have been taken. Should the pain and diarrhea still continue, give the 'Sun Cholera Mixture' in teaspoonful doses after each evacuation of the bowels." (*Pocket Cyclopaedia*.)

3. *PERTUSSIS: Etiology*.—The bacillus discovered by Bordet and Gengou.

"*Symptoms*.—The incubation period is from four to fourteen days, and is followed by a stage in which catarrhal symptoms, loss of appetite, fever, and restlessness are present. The paroxysms begin about the second week and consist of a number of short, spasmodic, expiratory coughs, succeeded by a long-drawn inspiration and a peculiar whoop, often terminating in vomiting. The eyes are suffused and the under lids are swollen and pinkish in color. The number of paroxysms may be very great, and this stage lasts from three to four weeks or longer. The symptoms then gradually ameliorate, and the stage of decline lasts two or three weeks longer. Convulsions, vomiting, bronchitis, and bronchopneumonia may complicate the affection. The outlook is favorable in uncomplicated cases.

"*The treatment* consists in isolation, proper feeding, protection from draughts, and the administration of atropine, belladonna, and antipyrin. Bromoform may be given to quiet the cough. During convalescence cod-liver oil, syrup of the iodide of iron, syrup of hydriodic acid, etc., should be administered."

4. *Wassermann reaction*: To the syphilitic antigen (extract of syphilitic organs) are added (1) the complement (fresh guinea-pig serum), (2) the suspected serum heated, (3) the amboceptor (heat-inactivated rabbit's serum), (4) the washed red corpuscles of the sheep, and the mixture is subjected to the action of incubator temperature. No hemolysis occurs by reason of the complement having been absorbed in the hemolytic series, the antigen and the serum tested being homologous. Such reaction is called positive.

Value. A well-pronounced positive reaction probably indicates the presence of syphilis; but leprosy, sleeping sickness and scarlet fever must be ruled out. Cancer is also said to give a positive reaction. It may indicate that the patient has syphilis, or that he has had it. The test requires elaborate technique at the hand of an expert.

5. *Rubeola* (better known as *measles*) is an acute infection and contagious disease, characterized by catarrhal symptoms of the respiratory mucous membrane, fever, and a mottled papular eruption which terminates by branny desquamation. *Symptoms.*—The prodromes are coryza, lacrimation, photophobia, hard bronchial or croupy cough, somnolence, irritability of temper, and sometimes convulsions. The temperature rises to 100° F. or 104° F. and increases until the rash is fully developed. On the second day hard papules of a dark purplish color may be seen on the palate, and on the fourth day an eruption made up of crescentic patches of small papules upon a slightly reddened base appears on the neck, forehead, trunk, and extremities. *Koplik's spots*—which are characteristic, minute bluish-white spots on a reddish punctate area—may be observed on the mucous membrane of the cheeks and lips, in the pre-eruptive stage of measles. They usually disappear when the skin eruption is at its height. The rash remains for from one to six days, after which the symptoms subside and a branny desquamation occurs.

(To be concluded.)

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE PRACTICE OF OBSTETRICS. By EDWIN BRADFORD CRAGIN, A.B., A.M., (Hon.), M.D., F.A.C.S. Published by Lea & Febiger; with 858 pages, illustrated with 449 engravings and 13 plates.

REFERENCE HANDBOOK OF THE MEDICAL SCIENCES. Vol. VI, Third Edition, completely revised and rewritten. Edited by THOMAS LATHROP STEDMAN, A.M., M.D.; 967 pages, illustrated by numerous chromolithographs and 490 half-tone and wood engravings. Published by William Wood & Company, New York. Price, \$7 cloth; \$8 leather, and \$9 morocco.

WOUND INFECTIONS. By Colonel Sir ALMROTH E. WRIGHT, M.D., F.R.S. Published by William Wood & Company, with 96 pages, and illustrations. Price, \$1.

THE AFTERMATH OF BATTLE. By EDWARD D. TOLAND. Published by the Macmillan Company, New York. 175 pages; illustrations. Price, \$1.00.

THE COLORADO INDUSTRIAL PLAN. By JOHN D. ROCKEFELLER, JR. Contains 94 pages.

INDEX OF TREATMENT BY VARIOUS WRITERS. Edited by Robert Hutchinson, M.D., F.R.C.P. and James Sherren, F.R.C.S. Revised by Warren Coleman, M.D. Published by William Wood & Company, New York; seventh edition, 1152 pages and 82 illustrations. Price, \$7.00.

PELLAGRA. By GEORGE M. NILES, M.D. Published by W. B. Saunders Company, Philadelphia and London. 261 pages; illustrated. Price, \$3, cloth.

INFANT FEEDING AND ALLIED TOPICS. By HARRY LOWENBURG, A.M., M.D. Published by F. A. Davis Co., Philadelphia, with 382 pages, illustrated with 64 engravings and 30 original full-page plates. Price, \$3.

STARVATION (ALLEN) TREATMENT OF DIABETES. By LEWIS WEBB HILL, M.D., and RENA S. ECKMAN. Published by W. M. Leonard, Boston, Mass., with 131 pages.

THOSE ABOUT TRENCH. By EDWIN HERBERT LEWIS. Published by The Macmillan Company, New York, with 326 pages.

TONSILS AND ADENOIDS, TREATMENT AND CURE. By RICHARD FAULKNER, M.D. The Blanchard Company, Pittsburgh, Pa. Price, \$1.

NEW CONCEPTS IN DIAGNOSIS AND TREATMENT. By ALBERT ABRAMS, A.M., LL.D., M.D., F.R.M.S. Published by Philopolis Press, California, 335 pages, with 80 illustrations.

ROADSIDE GLIMPSES OF THE GREAT WAR. By ARTHUR SWEETSER. Published by The Macmillan Company, New York, contains 272 pages, with illustrations. Price, \$1.25.

Miscellany.

Battlefield Casualties.—In the figures for the total British losses since the beginning of the war, recently given out by the War Office, the proportion of killed to wounded works out almost exactly in the ratio of one dead for each three wounded. This was for all the forces in all zones and classes of military activity. No differentiation for the casualties in trench warfare has as yet been given out officially, but certain reports indicate that in such warfare about one person is killed to each two wounded. These figures are interesting in comparison with the proportion of 1:4 which had been accepted before the war, and indicates that the kind of warfare which is being conducted bears directly on the amount and character of transportation and hospital facilities required in the zone of such warfare. Our accepted basis for estimates on the clearance of the battlefield will, like so many other standards, doubtless have to undergo material modifications.—*Military Surgeon*, January, 1916.

First Aid Instructions to Police Force of Baltimore.—Since the early part of 1914 first aid instructions have been given to the police force of Baltimore. Dr. Joseph M. Craighill, Chief Surgeon, began this work among the captains, but later decided to instruct the probationer policeman and installed it as a part of the curriculum at the regular school of instructions of this department at the Northern Police Station. Instructions have been along the lines of simplicity to enable the policeman to aid the sufferer until he could be taken to a nearby hospital; how to handle a man who had been overboard; how to get him to the ambulance; how to apply temporary splints, etc. These men are also taught what not to do, which is in many instances as important as the reverse. First aid packages containing a bandage, a pad to be applied over the wound, a triangular bandage, and two safety pins, have been placed in the lower part of each patrol box and are at the disposal, not only of policemen, but of any passing doctor who might be assisting in an accident case on the street. These packages have been placed also in each police patrol wagon together with an outer splint, to extend from the axilla down the side of the body, and an inner shorter one, and five leather straps to be used on various parts of the body. Instructions in swimming and how to rescue and resuscitate drowning persons have been given to the policemen around the waterfronts.—*Maryland Medical Journal*.

The Harrison Antinarcotic Law.—Two decisions by United States courts construing section 8 of the Harrison Antinarcotic Law have recently appeared. This section makes it unlawful for any person who has not registered and paid the tax under the law to have in his possession or under his control any of the habit-forming drugs named in the act, and such possession or control is made presumptive evidence of a violation of the act. The United States District Court for the Western District of Washington took the view that Congress intended to prevent the importation, manufacture, or sale of habit-forming drugs except as allowed by the law, and that the law should be so construed as to carry out this intention. The same section was considered by the United States District Court for the State of Montana about the same time. Judge Bourquin decided that section 8 applies only to persons who are required to register under the law.—*Public Health Reports*.

SIGNIFICANCE OF HEMORRHAGE IN OPERATIONS ON THE NOSE AND THROAT.

BY FRANCIS J. QUINLAN, M.D.,

NEW YORK.

PROFESSOR OF LARYNGOLOGY AND RHINOLOGY, NEW YORK POLYCLINIC; LARYNGOLOGIST AND OTOLOGIST TO NEW YORK CITY AND ST. VINCENT'S HOSPITALS; CONSULTING LARYNGOLOGIST TO THE NEW YORK FOUNDLING HOSPITAL, AND TO ST. JOSEPH'S HOSPITAL, YONKERS; TO ST. AGNES' HOSPITAL, WHITE PLAINS, AND TO THE JAMAICA HOSPITAL.

HEMORRHAGE, as a common and frequently fatal complication of operations on the nose and throat, was already known in ancient medicine. Cornelius Celsus recommended that the wound after incision of the tonsils be washed with vinegar and covered with hemostatic substances. The removal of the tonsils was altogether rejected by Rhazes in 950, as quoted by Velpeau, on account of the danger of hemorrhage; and Paul of Ægina refused to touch inflamed tonsils for the same reason. The loss of blood was likewise feared in cases of much enlarged and congested tonsils by medieval writers, such as Albucasis (1104), Brunus of Padua (1251), and Mercatus (1454). The same dread of hemorrhage in connection with nasopharyngeal surgery is expressed in medical writings of the sixteenth and seventeenth centuries, including Morgagni, in 1750, and several French authors in the *Journal de Médecine* of 1775. At this period, the operating surgeons were chiefly concerned with the avoidance or control of this type of bleeding. Not only were special instruments devised to arrest the hemorrhage, but remarkable suggestions were offered as to the wisdom of operating first upon the left tonsil, proceeding to remove the right only in the absence of hemorrhage. Even at the present day, when giant strides have been made on the prophylaxis and treatment of operative hemorrhage, uncontrollable oozing from the mucous surfaces of the upper respiratory passages still occasionally follows after intervention in this region.

For the better avoidance of hemorrhage, patients requiring operations in the pharynx or the tonsils are preferably operated upon in the sitting (upright) position, as the recumbent posture naturally favors the outflow of blood, by gravity. Before undertaking such a procedure on any patient, it is advisable to learn as much as possible of the personal and family history regarding previous tendency to exaggerated bleeding after slight injuries or minor operations, such as the extraction of a tooth, wounds, etc.

Operative hemorrhage may take place directly during the course of the operation, and it may be, more strictly speaking, postoperative, or delayed for a few hours up to several days. When the interval between operation and hemorrhage is considerably

prolonged, the bleeding is known as secondary. The clinical picture is variable, and the causes differ in the great majority of cases.

The parts most liable to bleed in operations on the nose and throat are, in the first place, the vessels of the cartilaginous and bony septum; and, in the second, the pillars of the fauces, especially the upper portion of the free margin of the posterior pillar. Interventions high up on the nasal septum are apt to prove more sanguinary than upon the lower part of this plane. Injuries of the plica triangularis or transversa are a common cause of bleeding. Not infrequently the pharyngeal mucosa is wounded through the straining of vigorous patients, and ragged wounds of this kind are a very frequent cause of bleeding. Over-radical and unnecessarily deep scraping of the fossæ of Rosenmüller sometimes interferes with the proper retraction of the divided blood-vessels, resulting in copious hemorrhage. Hardened and sclerotic adenoid vegetations are another prolific source of postoperative bleeding. In this connection, it may be emphasized that cutting instruments are more likely to cause bleeding than the snare, as evidenced by surgical operations on vascular lymphoid tufts at the base of the tongue, and in the Sluder method for the removal of the tonsils.

Delayed primary hemorrhage, coming on without an apparent cause soon after the operation, is usually due to the same pathogenic factors as direct hemorrhage, and is especially observed after the employment of cocaine or adrenalin; in consequence of secondary vasodilatation of the blood-vessels. Secondary hemorrhage, occurring weeks or many hours after the operation, is often extremely grave and is usually due to the detachment of a clot or the shedding of a scab, which is naturally favored by violent movements, such as walking, coughing, crying, vomiting, or clearing of the throat; it is one of the most serious aspects of postoperative hemorrhage; its onset is often abrupt and at night while the patient is asleep. Sometimes a dark blood clot (the physiological hemostatic plug) is vomited several days after the operation, and this is followed at once by profuse bleeding from the mouth and nose. Such hemorrhages are difficult of control and are very likely to be repeated with suddenness equal to that of the primary ones. The local blood-vessels in these cases have lost their elasticity and are sometimes greatly enlarged and varicose, as the result of chronic inflammation.

The etiological factors of hemorrhages, in operations upon the nose and throat, are divided in a general way into *local* and *constitutional*, both of which may be combined in a given case. There are four chief local factors, ranking in order of importance as follows:

Incomplete removal of tissue, due to faulty technique is a most common cause of bleeding. When

the bleeding is unusually profuse after operations in the nose and throat, it should always be kept in mind that a portion of loose tissue may have been left behind; the hemorrhage, as a rule, stops promptly after its removal. Proper trimming of the field of operation, at the hands of an experienced operator, removes one of the most serious causes of hemorrhage; for imperfectly detached tissue-fragments, left behind in the nasopharynx, will cause the vessels to remain agape, with the result of persistent oozing or outright bleeding. Wounds of the pharyngeal mucosa represent an important cause of hemorrhage.

Local lesions of blood-vessels are perhaps the next important cause of postoperative hemorrhage. A classification has been made into arterial hemorrhages, which are the most frequent on account of the fibrous stroma which keeps the vessels open; venous hemorrhages, through the incomplete division of the peripharyngeal veins; and capillary hemorrhage, which is usually referred to the hemophilic diathesis. Anatomical anomalies of the palatine and tonsillar artery, in the capsule of the tonsil, are largely responsible for traumatic hemorrhages of this kind. Fatal cases are on record in which the internal artery itself has been accidentally incised or punctured. Operative lesions of adjacent tissues, such as the pillars of the fauces, or wounds of the cheek, tongue, or lips, naturally result in more or less abundant hemorrhage.

Local tissue anomalies, such as severe inflammatory processes, on account of the resulting congestion, or mucous patches, on account of delayed cicatrization and wound repair, predispose to the occurrence of postoperative hemorrhage.

The general anesthetics, viz., chloroform, ether, and ethyl chloride, as well as nitrous oxide, etc., may be enumerated among the causes which operate locally, as they give rise to marked congestion of the vessels of the head and may thereby induce a very considerable loss of blood at the time of operation; while local anesthetics, such as cocaine, novocain, and eucain, are most apt to produce delayed hemorrhages.

Among the *constitutional* causes of hemorrhage in operations upon the nose and throat, by far the most important is represented by *hemophilia*. Other abnormal conditions of the blood itself, such as exist in purpura hemorrhagica, leucemia, and anemia in general, have also been held responsible for postoperative bleeding, likewise the blood changes incident to thyroid disease, notably exophthalmic goiter. The character of the blood is a factor of the greatest importance from the viewpoint of the operating nasolaryngologist, and in the best interests of both physician and patient the coagulation time should be ascertained before any surgical intervention is practised. In hemophilic conditions, the hematic organism endeavors of its own accord to increase the coagulability of the blood as a defensive act; and the existing deficiency in the production of fibrin ferment is advantageously supplemented by introducing into the blood stream some normal blood serum, which assists the organism to establish a new supply. Serotherapy has been found to be of value for the control of nasopharyngeal bleeding, both in topical and internal administration, but will be considered in detail under the constitutional the nose and from the throat, respectively.

The *treatment* of postoperative hemorrhage, with particular reference to surgical interventions in the nose and throat, is naturally divided into *local* and

constitutional measures. The former may be subdivided into those destined to relieve bleeding from the nose and from the throat, respectively.

Local measures for the control of postoperative nasal hemorrhage.—Unless the bleeding stops of its own accord while the patient keeps absolutely quiet for some time after the operation, perhaps with local applications of chopped ice, etc., it becomes necessary to insert tampons posteriorly or anteriorly. Nasal tamponing is a tedious and a disagreeable measure to be adopted, and should not be resorted to unless the bleeding spot cannot be located and the severity of the hemorrhage demands prompt attention. Posterior tamponage is to be resorted to only as an extreme emergency procedure for obstinate hemorrhages which refuse to be controlled by ordinary methods. Under no circumstances should tampons be left in the choanæ for more than twenty-four, or at most forty-eight, hours; as the retained secretions are otherwise apt to induce middle-ear infections, or even meningitis in especially unfavorable cases.

Pinching the alæ close together and bending the head forward, in order to hold the clot in position until organized, are the best, simplest, and most effective measures for the control of nasal hemorrhage. Local gelatin injections, although somewhat out of date, are sometimes useful and may be applied by means of a glass syringe, throwing into the nose twenty to thirty cubic centimeters of warm liquid gelatin, which promptly solidifies in the current of cool air in the nose. A highly ingenious but difficult and not always reliable hemostatic device is represented by Yankauer's method of stitching the posterior tip of the turbinal after nasal operations.

Local measures for the control of postoperative tonsillar hemorrhage.—The first rule is absolute rest—meaning that the patient must sit still, the head slightly inclined forward, without talking, gargling, or clearing the throat. He must also be cautioned against swallowing, and as this rule is not easily enforced, it is often deemed necessary to place a cork or mouth gag between the patient's teeth to prevent involuntary swallowing. This is a most important point, for the reason that the resulting traction on the constrictors forcibly detaches the newly-formed blood clot before it has been sufficiently organized. If the bleeding should continue, digital compression of the bleeding spot should be tried, the operator wrapping a finger of one hand in gauze, which is first dipped in hydrogen peroxide or a solution of antipyrin. The fingers of the other hand make counterpressure, or a tonsil compressor may be used for the same purpose, but the instrument must not be left in situ too long, so as to guard against pressure necrosis of the contused tissues. A simple but effective method consists in the application of towels soaked in ice water immediately after operations on the throat. This serves to regulate the superficial capillary blood supply through the relief of deeper congestion.

If the foregoing measures fail and bleeding persists, the tonsillar pillars may be brought together by means of large metal clamps, after a tampon of sterile gauze has first been pressed between faucial folds. A more complicated procedure consists in suturing the pillars together with two or three stitches, or in acupuncture and constriction of the bleeding stump. The most radical treatment, as a last resort, for uncontrollable hemorrhage in operations upon the throat is ligation of the common carotid artery—a serious operation, but not usually danger-

ous, or one interfering with the cerebral circulation.

Successive measures for the management of operative tonsillar hemorrhage.—(1) Application of local hemostatic agents, such as ice, oxygenated water, antipyrin, or horse serum. (2) Attempts at staunching the flow at its source from the blood vessel. (3) Local digital compression, lasting several minutes. (4) Injection of 20 to 40 c.c. of serum, combined with (5) Instrumental compression. (6) In persistent hemorrhage, suture of the pillars or acupuncture of the tonsil. (The purse-string suture for the control of postoperative tonsillar hemorrhage, recommended by Dawbarn, is not practicable in all cases.)

Precipitated blood sera, in the form of serum powder, have yielded favorable results in hemorrhages after tonsillectomies and turbinectomies. Not only has this serum powder been successfully applied as a local styptic to bleeding surfaces, as in oozing after nasal operations, but it has also been employed with good results as a prophylactic before operative procedures upon the nose and throat. Relatively large doses of the precipitated serum powder are recommended (0.6 to 0.7 grams, which is equivalent to 10 c.c. of whole serum). Prophylactic injections may be given the day preceding, or an hour before the operation; postoperative hemorrhage is guarded against by an injection one or two hours after the operation (Clowes and Bush).

Opinions differ as to the value of coagulin (Kocher-Fonio), a preparation made from animal blood plates, and usually employed on cotton swabs soaked in a solution. It is obtained through fractional centrifugation of mammalian blood, production of blood plates free from all blood elements, extraction of a cell-free solution of thrombozyme, and sterilization of this substance by boiling for fifteen minutes at 100°. Coagulin acts through hastening and strengthening the normal process of coagulation.

Constitutional Memostatic Measures.—Aside from hemophilic bleeding, there is a risk of postoperative nasopharyngeal hemorrhage in luetic conditions, and it is the author's habit, in suspected cases, to administer the therapeutic test as a routine procedure. In his experience, bleeding is often prevented by the internal administration of potassium iodide in 10 grain doses for a week prior to operations on the nose and throat.

In the treatment of operative hemorrhages from the nose and throat on the basis of a hemophilic diathesis, serotherapy seems to be specially indicated. According to Matas, "this mode of treatment, while not at all specific in character, is based on a rational principle, and has yielded sufficiently encouraging results since its introduction to deserve further trial, not only in hemophilia but in all the allied hemorrhagic states." The evidence collected from the literature is greatly in favor of serotherapy, practically no failures having been reported when fresh serum was used in sufficient quantities in conditions indicating its employment. When fresh normal sterile serum can be obtained it is to be preferred to the therapeutic antitoxic sera, as it contains all the desirable fibrin ferments (Matas).

The idea of utilizing serum for hemostatic purposes is based upon the observation that bleeding is checked by the application to the wound surface of blood from another individual. That local application of serum, however, failed to subdue the hemorrhage in intranasal interventions was the experience of Fleischer. He tried the subcutaneous injection

of 10 c.c. of horse serum in fourteen individuals known to have a strong tendency to hemorrhage. At the end of twenty-four hours after the injection the coagulation time of the blood was found to be lessened by six and a half minutes on an average. Subsequent operative interventions in the nose were associated with very slight or no hemorrhage, so that serum would seem to represent a useful prophylactic agent against hemorrhage in nose and throat surgery. If the bleeding is not controlled by the first administration of serum, little good can be expected from its continued use, according to Billings and Irons (1914). Sometimes a single dose suffices to check the hemorrhage. In cases of continued bleeding, the dose (10 to 30 c.c. subcutaneously, or 10 to 15 c.c. intravenously) may be repeated at intervals of two to six hours, or longer, depending upon the urgency of the conditions.

An interesting case illustrating nasal hemorrhage following turbinectomy in a hemophilic patient, treated by injections of blood serum, was reported by Linn Emerson in 1913. The patient, a man of thirty-one years of age, some thirty hours after the removal of the left inferior turbinate, had a profuse secondary hemorrhage of an alarming character. The bleeding was controlled by means of an injection of 2000 units of diphtheria antitoxin, and the nostrils were packed with cotton and gauze soaked in adrenalin. Precisely two weeks after the operation the hemorrhage recurred, and the following serum therapy was given: Serum was obtained from the blood of the patient's brother. On the first two days 20 c.c. were injected subcutaneously, three times daily, with immediate well marked results. The bleeding returned, although to a less degree, when the injections were again given, but were reduced to one a day. These injections were continued for nearly a week afterward. The patient's recovery was very slow, but no unfavorable symptoms of any sort were caused by this large amount of serum, more than half of which was derived from a donor unrelated by blood.

Although serotherapy often exerts a beneficial effect on bleeding connected with changes of the blood itself, the coagulation of hemophilic blood is not regularly accelerated in these cases, suggesting that aside from the retarded coagulation the condition of the blood vessels—perhaps the endothelial lining of the intima—also plays a part in hemophilia and other blood diseases. The blood vessels, as well as the heart, are stimulated by normal serum, which also possesses a natural stimulating action upon the various cellular elements, such as the leucocytes and red corpuscles of the blood. Upon the basis of practical experience in fifty operative cases serotherapy is advocated as a most potent and valuable ally in the control of hemorrhage by Goldstein. (Transactions of the XIX Annual Meeting of the Am. Laryngological and Otological Society, 1913, p. 256.) It is used by him as a routine procedure in nose and throat work, the coagulation time of the blood being systematically tested in all operative cases. Whenever this exceeds seven minutes, a serum injection is given.

The serum most frequently used is horse serum, which seems to yield more uniform satisfactory results than all others, and can be obtained in large amounts without difficulty. The frequent efficacy of antitoxic serum in postoperative hemorrhages is explained by the fact that fresh antidiaphtheritic serum also contains the fibrin ferment which is lacking in blood with an abnormal coagulation.

Endocrinic medication for the control of operative hemorrhage from the nose and throat is employed in the form of *adrenalin*, *thyroidin*, and, more recently, *pituitrin*. The latter, an extract of the posterior lobe of the hypophysis, has been successfully used by the Italian operator, Citelli, who reports excellent results, superior to those of the customary vasoconstrictors. The interventions in which pituitrin was efficacious included resections of the nasal turbinates, removal of polypi, tonsillectomies, and sinus operations. The injection of pituitrin is also recommended as a prophylactic, and Citelli injected 1 to 3 c.c. subcutaneously and intravenously without untoward effect; although 1 c.c. is usually sufficient, and is best injected from a quarter to half an hour before operating, to be repeated, if necessary, two to four hours afterward. The bleeding during sanguinary operations, such as inferior turbinatectomy or tonsillectomy, will be considerably diminished, as pituitrin exerts a well marked vasoconstrictor action, like that of adrenalin. It is preferable to the latter in so far as the influence on the vasoconstrictors lasts a much longer time, several hours up to a day, while the subsequent vasodilatation sets in very gradually, so that the newly-formed thrombus is not easily detached and the hemorrhage is permanently arrested. In the experience of Denker, pituitrin was found to be a valuable hemostatic agent, which frequently permits an almost bloodless operation upon the upper air passages. It was injected in doses of 1.0 gram in men, 0.5 gram in women and children, half an hour before the intervention, and was never followed by injurious effects. On the other hand, the enthusiastic claims of Citelli and others as to the hemostatic power of pituitrin are not indorsed by Donegan, who is not inclined to set aside adrenalin, or even hydrogen peroxide, as a method of checking operative nasopharyngeal hemorrhage. Pituitrin was employed by him in twenty-five cases, including five intranasal operations according to his method on the maxillary antrum, twelve middle turbinatectomies, and six tonsillectomies. In the case of the latter, for example, no difference in the amount of postoperative bleeding was perceived, except that it was certainly greater than in cases where adrenalin was employed. This is contrary to the experience of the writer.

As a constitutional hemostatic measure, calcium lactate has been recommended on account of its capacity of hastening the coagulation of the blood, its efficacy being especially marked in hemophilic cases. It was used by Simpson in hemorrhages associated with nose and throat operations, with an idea to their modification, if not prevention. He administered it for three days prior to operation and three days or longer afterward. In children the average dose of 20 grains three times daily was administered. These operations included septum and tantrum interventions, turbinatectomies, extirpation of adenoids, and tonsillectomies. From the results of seventy-five cases of the last-named groups, Simpson was convinced that calcium lactate not only controlled the bleeding at the time of operation, but that it was especially helpful in preventing secondary hemorrhages.

A few remarks may well be made in this connection on the prophylaxis of operative hemorrhage in nose and throat work. Children are far safer risks than adults, for age is a predisposing factor, and serious bleeding does not usually occur in patients under fifteen years of age. Postinflammatory

sclerotic changes of the tonsils are very common in adults, and the resulting scar tissue prevents the retraction of the vessels after the extirpation of the tonsil. No operation should be performed upon actively inflamed tonsils. In case the tonsils are known to be full of scar tissue, and the seat of fibrous degeneration, prophylactic serum injections are advisable. A general examination of the patient may reveal the existence of lues or of kidney or heart disease, which often involves a tendency to operative hemorrhage. More or less serious nasopharyngeal bleeding in nose and throat operations has been reported coincident with the menstrual period in women. It is therefore the part of wisdom not to operate during the week immediately preceding or following menstruation. As hemorrhage is especially apt to occur when the venous circulation of the face is obstructed and free breathing is hindered, it is essential that the patient's neck be not encircled by a high collar or other impediments.

The verdict of the laity to-day is to condemn us for any accident that may occur during or as the result of our surgical interference, and hemorrhage is not considered by them as an unavoidable accident, but rather as a sequence of our faulty technique in handling our cases.

Touching, in conclusion, upon the sequelæ of hemorrhage in operations upon the nose and throat, it is obvious that the general and inevitable result of profuse bleeding is anemia and exsanguination. Such a condition is particularly dangerous on account of its frequent combination with chronic diseases, and also when it occurs in patients who were already anemic prior to the operation. Recovery in these cases is apt to be prolonged, tedious, and sometimes interrupted by infectious diseases, recurring attacks of bronchitis, gastroenteritis and general exhaustion. Although fortunately rare, complications of this kind have been known to take place in the train of operative nasopharyngeal hemorrhages, and their development must be guarded against by directly combating the cause, namely, the post-hemorrhagic anemia. This means the institution of proper measures for the regeneration of the blood by means of rest, nourishing food, internal medication, and last, but not least, an abundance of fresh cool air and sunshine.

66 WEST FIFTY-SECOND STREET.

ARTERIAL DEGENERATION.*

BY CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK.

VISITING PHYSICIAN TO BELLEVUE AND TO ST. VINCENT'S HOSPITALS; PROFESSOR OF CLINICAL MEDICINE, CORNELL UNIVERSITY MEDICAL COLLEGE, NEW YORK CITY.

DURING the past fifty years modern inventions have revolutionized methods of living, and in place of a comparatively easy-going existence, life has developed into a strenuous, uneasy, nerve-racking struggle. This is especially true of life in the large cities where amusements must be deferred until the evening, or until far into the night, while the days are spent in the excitement of keen, almost fierce, competition. To be sure, the city dweller has advanced intellectually, but physically he has deteriorated, in spite of the fact that preventive medicine has in recent years saved the lives of thousands by improving the food supply, and by discovering the way to control certain of the infectious diseases. The tissues of which the human organism is constructed do not seem able to meet the demands of the present day existence, in the centers of population. Breakdown occurs early in those who fill the important places in our community. What are the causes of this premature decay?

Success in war is not so much a question of men and money as it is a question of bread and meat. The efficiency of entire armies has been seriously jeopardized by difficulties in the commissary department. This has been illustrated in Cuba, in South Africa and in the Russo-Japanese conflict. The present European war will probably not be ended until the productive fields of central Europe have been saturated by the blood of countless victims and the food supplies brought to an end. The history of a military campaign may be aptly compared to the battle of life, which the tissues of the human body are constantly undergoing. In this battle there is constant effort to make up for inevitable losses, to maintain the position already gained, and to seek further advance, all in the face of the powers of wear and tear which threaten disability or total extermination of the forces engaged,¹ and the final result will depend upon the integrity of what are technically called the physiological processes of nutrition. It is purely a question of food supply. In the human body the circulatory system constitutes the commissary department. The blood vessels are the purveyors of its nutrition. They deliver the proper kind of nutriment required by each individual part. They do not leave powder and shot at the field hospital and send carbolic acid to the firing

*Read before the Essex County Medical Society at Newark, New Jersey, February 9, 1916.

line, but each ultimate tissue of the body receives, during health, the material proper to its rebuilding. More attention has been directed to the blood-vessels during recent years than was formerly accorded. The arteries show more truly than the family calendar the age of the individual.

To appreciate properly the importance of the arteries we must remember that these vessels are not mere inert tubes for the conduction of the blood, but are really vital organs. Vital they certainly are, not only as being necessary to life, but vital in the other sense of being living tissue, a living part of a living whole.¹ It is in the arteries and their terminal branches, the capillaries, that the ultimate processes of life take place. It is upon these vessels that the stress and strain of our daily life must fall. There is no doubt that arterial disease is more frequent than it was twenty-five years ago, and that the deaths from diseases which depend upon changes in the blood vessels are increasing. One of the most frequent causes of this increased mortality is the high tension under which business is done in this country and the fierce competition for material success. Among our own profession, sedentary habits, protracted and intellectual work, emotional disturbance, anxiety, grief, and a sense of responsibility, either directly disorder blood pressure or indirectly cause disturbances of digestion and metabolism, which load the blood with excrementitious substance. As a consequence, death reaps a harvest among medical men from the three-fold results of arterial disease, to wit: Bright's disease, apoplexy, and heart disease. It has been shown by the Health Department records of New York and Brooklyn that the death rate of medical men from these three causes is exceeded only by that of saloonkeepers, who are supposed to be intemperate; by that of butchers, who are thought to be gluttonous; by that of quarry men, who are exposed to the dangers of explosives and inhalation of irritant dust; and by that of factory operatives, who are usually underpaid and underfed. No apology is therefore necessary for inviting the attention of working physicians to the importance of a careful study of this subject.

To detain you with an exhaustive description of the anatomy of the blood vessels would transcend the limits of this paper and exhaust your patience. It will only be necessary to recall that the walls of the vessels are three in number; the outer wall, chiefly fibrous, carries the nutrient vessels and gives strength to the structure; the middle wall is muscular and elastic; it receives the nerve supply and is the essential factor in the regulation of the circulation and the distribution of the blood. The whole vascular system, including the heart, has an endothelial lining, which may constitute a distinct inner coat, the tunica intima, or may be without coverings, as in the case of the capillaries. The essential portion of any blood vessel is this endothelial tube, composed of flat cells cemented together by intercellular substance and having no stomata between the cells. The whole circulatory apparatus is under the control of the nervous system, which acts not only directly upon the heart, but also on the vessels themselves, in whose muscular walls there are "local hearts," and these local hearts regulate local pressure, and have, moreover, immediate connection with the central heart. The increased complexity of our modern life causes increased wear and tear upon this complicated circulatory apparatus, and the brunt of the wear and

tear falls upon the arteries. Hence, the old saying, "A man is as old as his arteries," is, if anything, more true to-day that it was when the axiom was first uttered. Various names have been suggested to describe this diseased condition of the arteries, and the term, arteriosclerosis, like "that blessed word Mesopotamia" in the Highland lady's system of theology, has become so fastened in our minds by repetition that it is difficult to understand that the word has not in every case the same constant and sharply defined significance. This is due, of course, to the fact that the secondary results of degeneration of the arteries are so multiform in their manifestations and so widespread in their distribution as to require a distinguishing subdivision in any individual case. How then shall we define arteriosclerosis?

Arteriosclerosis is a hyaline degeneration of the structural elements of the arterial wall, with connective tissue substitution, hyperplasia, and subsequent contraction with induration, whereby the characteristic functions of the vessel wall—retention, absorption, metabolism, with the power of expansion and contraction, are weakened and lost.^{2,3} The hyaline process is usually associated with atheromatous and often with chalky and fatty changes. Atheroma may be regarded as the physiological form of thickening of the arterial wall, which is the usual accompaniment of advancing age. Arteriosclerosis is, on the other hand, the pathological form of disease of the arterial wall and may arise in early life, in childhood, or even in infancy. Arteriosclerosis may exist without atheroma, and atheroma without arteriosclerosis, though frequently both are manifested in the same subject.

Whether the first pathological change in arteriosclerosis begins in the blood, or in the blood-vessel wall, or in the nervous system, has not been determined as yet, but the tendency of modern opinion is to locate the origin in the blood. The first effect of arteriosclerosis in the vessels shows itself in the impairment of contractility, and later in weakening of elasticity and osmosis, and consequent interference with metabolism; next in the escape of fluid constituting the various dropsies and the exudation of albumin from the walls of the vessels of the Malpighian bodies; finally, in the failing nutrition, emacipation, and marasmus which mark the terminal stage of the disease. The increased resistance in the vessel throws extra work upon the heart, which first hypertrophies and then dilates. We are apt to forget the enormous amount of work which the heart is called upon to perform during a life time. It has been calculated that each pulsation of the heart is equivalent to a force of two foot pounds; a heart beating 72 times a minute will thus expend an energy equal to 144 foot pounds, or 8,640 foot pounds per hour, or the enormous total of over 100 tons of work in 24 hours. When arterial disease throws more work upon the heart, the heart muscle tries to overcome the increased resistance by more forceful contraction and accomplishes this by an increased size of the muscular fibers and also by adding additional new fibers. For a while this addition compensates for the increased labor of the circulation and the patient is comfortable, but after a time the obstruction become too great to be overcome by the increased power of the heart muscle, and slowly and stubbornly the heart yields, its chambers become enlarged, and the valves, which should accurately close the chambers, begin to leak. If, however, the heart continues strong and the ves-

sel grows weak we may have distention of the vessel wall, giving aneurysm, or rupture, causing apoplexy. As the arterial system was first in the development of the human body, so also is it that upon which the finger of decay is earliest laid. It is sometimes impossible to foretell whether the damage will first be done to the heart, the vessels, the kidneys, or the brain.

The causes of arteriosclerosis fall under the headings of heredity, age, sex, alcohol, syphilis, acute rheumatism, certain acute infections, high living, and hard work. As Osler has tersely said, the onset may be said to depend in the first place upon the quality of arterial tissue (vital rubber) which the individual has inherited, and secondly upon the wear and tear to which he has subjected it. Our parents determine to a great extent the kind of tissue with which we start life; we ourselves may control the factors which tend to injure this tissue. Age is also a factor beyond our control, but according to comparative anatomy man is entitled to live 100 years if he conserves his energy by self-denial, protects himself as best he can against disease, and is able to secure the comforts of life. Age is a very indefinite expression; one man may be old at 30, another may be young at 60. Lives of self-denial may enjoy a corresponding reward of longevity; lives of self-indulgence receive the punishment of premature senility. Of course the gross alteration of atheroma cannot be prevented but the finer changes of arteriosclerosis may be postponed or eliminated by our own care. Sex enters into the question insofar as men are more frequently affected with alcoholism, syphilis, gout, and are subject to more mental and physical strain than the average woman. Alcohol acts in many ways to cause arterial degeneration. It over-excites the heart so that the vessels are subjected to greater strain; it disturbs digestion, causes liver cirrhosis and kidney insufficiency, which load the blood with poisons; lastly, alcohol is itself a poison to the blood. Syphilis causes so much thickening of the inner walls of the vessels as to lead to great diminution or even obliteration of their caliber. Disease of the intima is, however, always secondary to disease of the media, in which infection first takes place.⁵ Syphilis may also deposit gummatous nodules in the outer wall. The *Spirochetes pallida* has been found in the degenerated vessel walls and in the gummata.⁴ Since the discovery of the Wassermann reaction the syphilitic origin of arterial disease has been demonstratively proven. Syphilitic changes will affect the brain by preference, because syphilitic arteritis is localized in arteries supplied with lymphatic sheaths. Certain acute infectious diseases, especially typhoid fever, malaria, influenza, scarlet fever, and diphtheria, may cause arteriosclerosis either by injuring the vasomotor nerves, or by directly affecting the endothelium by their specific microorganisms or toxins. Thayer and Brush have found the arteries more palpable in those who have recovered from an attack of typhoid fever than in average individuals of equal age who have never had the disease. Chronic diseases, like gout, rheumatism, and diabetes frequently produce changes in the vessel wall. Poisons like ergot and lead produce contraction of the smallest vessels, thereby increasing blood pressure and throwing extra work upon the heart and vessels. Over-feeding and excessive drinking induce a simple plethora of the vessels, and in addition load the blood with poisons. Hard work acts by raising the blood pressure and subjecting the

heart and the vessels to strain, especially if the work be accompanied by depressing emotions or accomplished under circumstances of prolonged mental or physical strain. Muscular overwork deserves more consideration than has hitherto been given it. We see it as an etiological factor, especially among the laboring class, in both whites and negroes, possibly because this class indulges in coarse heavy food and in alcohol. The high tension produced by athletic training has also been brought forward as a cause of premature failure of the heart and blood vessels. To what symptoms and physical signs does arteriosclerosis give rise?

The story of arteriosclerosis is not the story of the past few weeks, but must comprise the life history of the patient from his cradle, and often include that of his forefathers also. It is doubtful if the sclerosis itself could produce symptoms were it not that the organs supplied by the diseased arteries suffer from an insufficient blood supply, and the symptoms then arising become referable to any or all of the affected organs. The symptomatology sometimes makes the diagnosis easy and certain; sometimes only presumptive; sometimes impossible. The disease may be latent for a long time, the symptoms occurring only after effort. In the diagnosis of latent arteriosclerosis the invention and perfection of blood pressure apparatus has afforded us valuable assistance. The instrumental determination of blood pressure is regarded by the laity as something new, and has been made the subject of much satirical jest by our professional humorists, and by the class of playwrights who cater to the individual known as the tired business man. One of these humorists has recently written that the real advantage in knowing what one's blood pressure is lies in the fact that it gives one a new thrill of terror. As a matter of fact attempts to determine blood pressure for man by instruments began in 1855, when K. Vierordt placed weights on the radial pulse until this was obliterated. The first useful instrument, however, was devised by Marey, in 1876. V. Basch, in 1887, devised an instrument which was used to some extent. This instrument recorded only maximum pressure. In 1896 and 1897 the present flat rubber bag encased in some non-yielding material was used by Riva-Rocci. This instrument, with its various modifications, is the one in general use to-day. The instrument devised by Dr. Rogers has also met with considerable popularity. It is hardly necessary to say to this audience that it is most important to estimate accurately the diastolic pressure as well as the systolic pressure,⁶ for only in this way can we obtain any data of value regarding the driving power of the heart and the condition of the vasomotor system, nor it is necessary to emphasize the fact that high blood pressure may be conservative and that we must not rush at it madly with a big stick.⁹ It cannot be too frequently emphasized that high pressure may exist without arteriosclerosis or arteriosclerosis without high blood pressure.⁵ It would lead us too far afield to attempt to discuss the great variety and protean character of symptoms and physical signs which may be manifest in a disease which is capable of carrying its destructive work into the ultimate living cells in any or every important organ in the body. It must suffice to say that when the aorta suffers we may have aneurysm with its accompanying train of symptoms or of physical signs. When coronary arteries are involved we have heart failure, arrhythmia, and stenocardia. Thickening of the

bronchial and intercostal arteries may give weak respiratory efforts, defective expansion of the chest, and emphysema of the lungs. In the classical arteriosclerotic kidney we may have abundant urine of low specific gravity, little albumin, hypertrophied heart. Brain symptoms at first require keen observation, or rather keen perception, on the part of the patient himself; earlier fatigue, disinclination to effort, especially to the effort which has perhaps made the man successful in life; irritability, alteration of disposition, headache when in bad air. Headache after the very moderate use of alcohol, tobacco or coffee are all danger signals to the man over 40 years of age. In the vessels of the extremities, coldness of the surface, rheumatoid pains on walking, the vasomotor phenomena of Raynaud's disease, the remarkable condition first described by Charcot known as intermittent claudication, may be evidences that the stiff vessels cannot accommodate themselves to changes in the necessary vascularity of the part. The ocular signs and symptoms are most important in early diagnosis, and the ophthalmologist may be the first to recognize them. With the improved electrically lighted ophthalmoscope now upon the market, characteristic changes in the retina and disc may be readily discovered by the general practitioner.¹⁰

The diagnosis of early changes in the arteries among young persons depends largely upon how carefully these changes are looked for. The obvious advantage of early recognition of the disease need not be dilated upon. Even the tyro in medicine will have no difficulty in recognizing arteriosclerosis when it has advanced to the combination of hypertrophied heart, increased blood pressure, palpable arteries, and ringing accentuated aortic second sound. Even then much may be done to ward off complications and prolong life, but we should not wait until such signs are apparent before making the diagnosis and instituting treatment. The history of the case is the first essential. A good history is half the diagnosis; in some instances, the whole diagnosis. It should include the personal habits of the patient, a record of all his preceding infectious diseases, and an inquiry into his family history, especially with regard to gout, rheumatism, and alcoholism. More potent than all other diseases to cause arteriosclerosis is syphilis; not only the fact of actual infection, but the duration and thoroughness of treatment should be carefully studied. The patient's occupation should be carefully noted. Athletes, laborers, brain workers who are under constant mental strain, and those whose work brings them into contact with such poisons as lead, present every factor necessary for the development of arteriosclerosis. The use of tobacco is a much debated question. Personally I am convinced that moderation in the use of tobacco is not attended by any of the dangers which fanatics ascribe to it. Of much more importance is the habit of overeating. Overeating is the curse of the American people. An excess of food distends the capillaries with blood; capillary resistance is increased, with stretching of the arteries and consequent damage to the walls. The successful business man of florid type, who works all day, drinks from three to seven whiskeys, is proud of his physical development, and boasts that for more than twenty years he has never had a doctor, is sometimes astounded when his application for life insurance is rejected because of palpable arteries, beginning heart hypertrophy, and high blood pres-

sure. People should be taught that at least twice a year they should be carefully examined by a doctor who has the time to go through every step of a systematic examination. The public are beginning to realize the importance of this, as is evidenced by the number who submit themselves to such periodical examination.¹ In this way we may hope in the future to make the early diagnosis of arteriosclerosis much more frequently than it has been made in the past. It must be remembered, however, that arteriosclerosis may be marked in some vessels and so slight in the peripheral vessels that it cannot with certainty be made out. Particularly may this be true when there are marked changes at the root of the aorta, leading to sclerosis of the coronary vessels alone, and giving no symptoms until an attack of angina pectoris sends the patient to a physician. When true angina pectoris occurs it must be carefully differentiated from pseudo angina pectoris, which usually occurs in neurasthenic individuals; or from toxic agents; in which no age is exempt; in which the paroxysms of pain are periodic and often nocturnal; in which there is no sense of real anguish; in which the duration may be an hour or more; in which restlessness and emotional symptoms are usually prominent; in which there is no increase in arterial tension; and which has a favorable prognosis. True angina pectoris, on the other hand, is associated with coronary arteriosclerosis or with aortic regurgitation; is rare before 40; usually affects males; rarely has periodicity of the paroxysms; there is a sense of impending dissolution; the attack lasts only from a few seconds to several minutes; the patient has a silent and fixed attitude, the suffering being too intense for emotional display; the arterial tension is increased as a rule, and the case presents a most unfavorable prognosis.⁴ What is the outlook for the patient with arteriosclerosis?

In a disease so protein in its manifestations it is not possible to give a certain prognosis. The chief factors to be considered are, (1) the seat of the sclerosis; (2) the probable stage; (3) the existing complications, and last and most important, the patient himself. It is much more dangerous for the patient when the disease affects the root of the aorta than when it has attacked the peripheral arteries. When the kidney arteries are involved the disease is usually bilateral and widespread and symptoms of renal insufficiency may appear at any time and rapidly prove fatal. In the peripheral arteries very serious, even fatal, results may be brought about by interference with the circulation, with resultant extensive gangrene of the part supplied. In the larger vessels there is danger of aneurysm in the early stages of the disease before the artery or arteries have had time to become strengthened by proliferation of the connective tissue. In the brain, apoplexy, either slight or severe, may occur. The first attack of cardiac asthma is to be looked upon as the beginning of the end. In the kidneys it is not always possible to determine the extent of the kidney lesion by urinary examination. In the intestines, arteriosclerosis of the splanchnic vessel may give embolism or thrombus, or intestinal hemorrhage. In giving a prognosis the general condition of the patient, his build, physical strength and powers of recuperation, etc., must all be taken into account. It is the whole patient that we must consider, and not any one symptom that at the time happens to be the occasion of greatest trouble. The willingness of the patient to follow the directions

of his physician also determines to a great extent the prognosis.

With regard to the treatment of arteriosclerosis it is impossible, of course, to lay down definite rules. The keynote is individualization. The laboring man must be differently managed from the successful financier. One may treat fifty patients who have typhoid fever by a routine method and all may recover. Far different is it when treating a disease like arteriosclerosis. The successful treatment of the latter cannot be learned from text books, nor pointed out within the limits of any paper. It requires the tact, the intuition, the knowledge of human nature, the subtle something, that makes the successful therapist. For those who cannot get out-of-doors, exercise in the room with the windows open must take the place of out-of-door sports. As a tonic or invigorator the cold or cool bath in the morning, on arising, can be highly recommended, but it is folly to urge it on one to whom it is distasteful, or on one who does not feel a comfortable glow or reaction after it. Turkish and Russian baths should be absolutely condemned, because the increased force of the heart beat that accompanies a hot bath might be sufficient to rupture a small cranial vessel. Obstinate constipation should be sedulously avoided. The use or non-use of alcohol in advanced life has been the subject of so voluminous a controversy that each man must dogmatically express his own opinion. My personal conviction is that alcohol is an entirely unnecessary addition to the diet of any individual in health, although it may be needed in sickness. Of the three classes of foodstuffs it may be said that excessive protein consumers are more apt to develop arteriosclerosis comparatively early in life. The harmful effect of over-indulgence in fats and carbohydrates is the extra work that is put on the heart by formation of many new blood vessels in the adipose tissue derived therefrom. For patients who have any form of arterial disease an excess of fluid is harmful as it results in a condition of plethora, which necessarily reacts injuriously on the heart and circulation.

With regard to the use of medicines in arteriosclerosis it has long been thought that iodides of potassium and sodium have a favorable effect. It is difficult to obtain exact knowledge on this subject. Romberg and others believe that iodide has its favorable effect not upon the vessels, but upon the blood viscosity, which in nine out of eleven men was reduced. Other observers have been unable to corroborate these findings.⁶ It is possible that the iodides owe their reputation in this disease to their influence upon syphilitic arteritis. Thyroid extract in very mild doses, grain one-third, morning and evening, has been found to lower blood pressure, possibly on account of its iodine content. Sodium nitrite and erythrol tetranitrate may benefit some cases, but are uncertain in their action. The effect of nitroglycerin is transient unless given every hour, as it is believed that its elimination is accomplished in 30 minutes. No dogmatic rule for dosage can be laid down with regard to the individual reaction of these drugs. I have given 10 drops of the 1 per cent. solution of nitroglycerin every hour before a manifest effect was secured. The nitrites have decided value but they have their limitations. In angina pectoris or in attacks of cardiac asthma inhalation of amyl-nitrite may be useful. A drug much in use in my wards in Bellevue Hospital, for the reduction of high blood pressure, when this

is not compensatory, is tincture of aconite. But the most important measure for the relief of acute high tension is absolute rest in bed with limitation of the diet, as in the Karell cure. In milder cases, the patient should spend from 10 to 14 hours daily in bed, and the urinary output should be measured and compared with the liquid intake. Venesection is used by us in threatening eclampsia, and with marked benefit. Hot packs or sweat baths assuredly do reduce the pressure in many cases. The function of the skin should be stimulated by frequent baths in all cases. The Nauheim method equalizes the circulation, besides assisting cutaneous elimination. In the attacks of dyspnea, which occur in the late stages of arteriosclerosis, morphine is invaluable; it relieves spasm, quiets the cerebral centers, and is an actual heart stimulant under such conditions.

With the use of the Trunecek serum I have had no experience, as I was not convinced by the early favorable reports. Digitalis cannot be expected to act on the diseased myocardium, which is a secondary result of arteriosclerosis, with the same benefit as occurs in the dilated heart consequent upon valvular lesion. Radium and the high frequency current of electricity have been enthusiastically praised by those who administer them. I have had no experience with either and can neither commend nor condemn.

How can we defer the advent of old age?

We cannot live without the heart beat, and the prevention of arteriosclerosis compels us to remember Herbert Spencer's definition of life, *i.e.* that it is "the continuous adjustment of internal relations to external relations." In this adjustment of our lives to our environment we must strive to get the maximum of work accomplished with the minimum amount of wear and tear on the blood vessels. Competition in every profession is now so exceedingly acute that to rise to prominence in any branch requires exceptional powers of mind and body. We live rapidly, burning the candle at both ends, and it is not strange that so many comparatively young men and women grow old prematurely. It is not the work, but the worry, that leads to arterial degeneration. Hard work in these competitive times is a thing but few can avoid, but, fortunately, it need not be shunned through fear of harmful effects, for, if taken up with a cheerful, contented mind, it will strengthen and develop rather than weaken the bodily forces. But the secret of successful hard work is happiness; not pleasure, for pleasure is only the gratification of our animal nature, and pleasure depends upon the possession of things, but things decay; not joy, for joy is the satisfaction of our social nature, and joy depends upon the possession of friends, but friends die. Real happiness is the fulfillment of our spiritual desires, and depends upon the possession of character, and character is immortal. He, who, in the prime of life, has learned this secret of happiness, can bid defiance to the enemies of advancing years. He can accept prosperity with equanimity, and he can fight adversity with courage. He knows that prosperity does not *bind*, it merely *assembles* people—at dinners and dances; it is adversity that *binds*, and that draws around one the real friends that enable him to meet it. In addition to the development of character we should endeavor to have a diversification of interests. Hobbies are sometimes the salvation of men. Moderation in all the duties and pleasures of life is the keynote of the prevention of arteriosclerosis. This does not mean that a man must nurse himself into

neurasthenia for fear that something will happen to him, nor deny himself the legitimate pleasures of the social table or the healthful dance. As one grows in years exercise should not be violent, and food should be taken in smaller quantities. Of the forms of exercise for middle or advancing years, walking and golf are beneficial, particularly the latter, provided that the 19th hole be not played too often.

42 EAST TWENTY-NINTH STREET.

A PRACTICAL SCHEME TO IMPROVE THE PHYSIQUE OF AMERICANS.

BY RICHARD COLE NEWTON, M.D.

MONTCLAIR, N. J.

LATE PRESIDENT NEW JERSEY STATE BOARD OF HEALTH; CONSULTING PHYSICIAN TO THE MOUNTAINSIDE HOSPITAL, MONTCLAIR.

HUMBOLDT declared that "Whatever virtue men would have appear in society must be taught in the schools." It is upon these nurseries of civilization that we must rely to reawaken the physical conscience, and to show to future generations that, by taking thought, they can not only free themselves from disease, but can attain a vigor of intellect and a strength and beauty of body not seen on earth since the days of the ancient Greeks.

The following plan is proposed as a direct and efficient method of teaching the masses what the body beautiful should be, and what steps are necessary to secure this great desideratum.

The number of teachers and experts necessary to carry it out will be no greater than the extra teachers now employed in our public schools to distract the children's minds from the fundamental studies of the curriculum by inculcating in a vague way a smattering of various more or less immaterial subjects. Teachers, parents, and everyone else at this writing, acknowledge that health comes first, and that the whole system of education must be made to conform to this axiom in very deed, even as it now professedly conforms to it in theory.

To begin with, we must fain acknowledge that there is no question that much of the present drive to conserve and improve the health of school children begins too late. It is in the improper treatment of the little children that most of the seeds of future trouble are sown. If small scholars were carefully watched, and each one minutely studied for any congenital defects, as well as for any fault of environment, there might result an enormous saving to the State by reason of the diminution in the numbers of dipsomaniacs, neurasthenics, insane, and incompetent people. Starting the education of numbers of congenitally defective children in

our public schools, and pushing them along, until their condition is made worse and harder to remedy, is an error which we are learning to avoid. But we are not so careful to avoid and not so successful in combating injury not alone to the delicate, under-developed, and under-nourished children, but even to the normally healthy ones, by improper physical conditions in the schools.

The principal reason for this failure, which is so far-reaching, and so general that its importance cannot be overestimated, is that we neglect the physical status of the young scholar until more or less harm has been done. We are trying to make bricks without straw by pushing all the young scholars along the road of education just so many feet every year, all the while neglecting the two essential features, first, whether the child has the normal equipment, physical and mental, for the work, and second, whether the work is in any way injurious to him.

School teachers have a notion that so long as the child keeps up with his grade, and no complaints of ill health are made, he is doing well enough and there is nothing to worry about. There are a great many rules and tables to determine what the mental status of a child should be at a certain age, and for that matter, there are enough rules to show what the average child's physical development should be at a given age. Unfortunately, however, the teachers do not know the latter rules, however well they may be acquainted with the former; nor are there any tests of the physical status of the scholars in the regular school work that are as easily applied and as efficient as the tests of their mental work, always at hand in their marks for their recitations and their periodical examinations.

Consequently the average teacher is not at present capable of judging whether the child is being injured by the school work, or whether the child has the normal physical development for his age. The medical inspector of the school is not engaged to do this essential work, so it is not done.

There is, therefore, not only the danger of a lasting injury to the child by allowing him to live under improper conditions, both in and out of school; there is also, the further unfortunate circumstance that his physical development is neglected. From both of these causes the average school child suffers injuries that are most vital, both in their immediate and remote results. "As the twig is bent, the tree is inclined." Our interference with present conditions must not be solely of a negative character; we must take positive steps to assure the best mental and bodily development if we wish to give every scholar a fair chance to grow up to the full measure of his potential abilities. As an incentive to everyone directly interested in this vital question, the parents, the teachers, and especially the child, the following simple plan is proposed: To begin with, there should be careful physical examination at least monthly, of every scholar by qualified inspectors under the control of the medical inspector of the school. The teachers could easily learn to assist the medical officer and should perform most of the detail work necessary for the proper examination and rating of their own scholars. This aspect of the matter will be taken up again further along in this paper.

Cards should be made out in duplicate, scoring the child, as dairies are now scored. Height,

weight, lung capacity, strength, etc., etc., should be recorded and compared to the normal for the scholar's age. The condition of the eyes, teeth, tonsils, throat, hands, feet, and genital organs should be noted. Special examination should be made for rupture, undescended testicle, scoliosis, enlarged veins, enlarged thymus and thyroid glands and abnormal conditions of the lymphatic glands, spleen, and liver. The state of the tongue, conjunctivæ, complexion and skin generally, should be noted. Also the care of the body, whether clean or dirty, whether the finger and toe nails are clean and well trimmed, whether hair and scalp are clean and properly cared for. Bow-legs, knock-knees, enlarged joints, flat feet, or any malformation or disease of the bones should also be especially noted. Credit should be given for everything normal, and extra marks might be allowed for especially good points, like a perfect denture, marked cleanliness of body, etc., while certain specified reductions in the marks should be made for congenital malformations such as club-foot, flat-chest, strabismus, hunch-back, etc.

One of the aforementioned cards should be sent to the parent or guardian and one filed in a card-index to be consulted at the next examination. Stooping shoulders, spinal curvature, corns, eruptions, ringworm, itch, decayed teeth, pediculosis, spongy gums, coated tongue, and other remedial conditions should be reported and, if reasonable efforts are not made to correct them, the child should be debarred from a rating at the next examination. This would endanger his chances in competing for the health and beauty prize, to be hereafter described. If especially good corrective work has been done, extra marks might be allowed.

This monthly rating should be continued until the child graduates from the primary or grammar school and at the close of each school year there should be an accounting. If the marks for physical rating for the year fall below a certain minimum the pupil should be debarred from promotion to the next grade in the school. If, however, the aggregate of credits exceeds the minimum, a medal for good physical condition should be presented to the child, and if the total credits reach a specified height, extra credits should be granted. The medal may be of some ordinary metal, as copper, or brass, but pretty enough to be attractive. Absence from school for sickness or otherwise should be noted in the summing up of the marks, and might affect the rating. The minimum in the lower grades, at least, should not be placed so high as to debar an average child, whose parents or guardians will make a serious effort to correct the defects noted.

A certificate should be awarded to each scholar who has received the required number of credit marks, and special note should be taken of all scholars whose record shows great improvement in physical conditions since the marking began. All the scholars who receive these certificates, and who are otherwise eligible, may enter the competition for the health prizes. These prizes shall be sufficient in number so that one may be given every year to that boy and that girl in the graduating class of every primary and grammar school in the city or town, where this plan shall be adopted, who shall pass the best physical examination and who shall present the best series of marks for physical rating for their entire course in the school. The grammar school prizes shall be \$500 each in money, and a handsome medal (or certificate). One

shall be given to a boy and the other to a girl. Under the same conditions, two prizes of \$50 each, shall be given to two primary school graduates.

Before a graduate of the grammar of primary school may compete for one of the health prizes certain conditions must be fulfilled: (1) Their marks for health and physical excellence must, in the aggregate, reach a high percentage, say eighty or ninety per centum, for their whole course in the primary or grammar school. (2) The candidate must have a mark in all the studies of the school course above the average marks given the entire school. (3) There must be nothing known against the candidate's habits or character either in or out of school. The boys must never have been detected in any flagrant violation of the rules of the school, or in any form of lying or deceit, or in the use of liquor, tobacco, or profane language, and the girl candidates must not have been reprimanded for any infraction of the rules of the school, for impertinence, nor any impropriety of conduct, wearing improper clothes, or treating their parents or teachers disrespectfully, or for deceit or idleness. In short, before permitting a scholar to compete for the prize each applicant must furnish a certificate from the principal of the school or schools, which he or she has attended, covering all the points mentioned.

The examination should be conducted as follows: Each candidate must be a member of the graduating class of the year in which the prize is given, and must show the health cards awarded him or her for every year of their entire course in the primary or grammar school. If part of this course was spent in any other school in the same town, and where the same rules are observed for marking the physical condition, a scholar who has changed from one primary or grammar school to another may present the cards and certificate awarded him in the school he first attended, and may be eligible for the prize to be awarded in the school where he graduates. He must have presented a request to be examined for the health prize at least a month before graduation.

There shall be for the town or city, appointed each year by the Superintendent of Education, the President of the Board of Education, and the Commissioner of Health, or the President of the Board of Health, an examining board, to be composed of the Superintendent of the Schools, the President of the Board of Education, and the Health Commissioner of the town or city, or in cities where there is no Health Commissioner, the President of the Board of Health; these shall be members of the board *ex officio*. Besides these there shall be at least eight members of the board. Of these three shall be men and three women, who shall be experts in physical training, and at least one of them shall be a male and one a female physician. In addition, there shall be two artists or sculptors of reputation members of the Board, one of whom shall be a man and one a woman.

Of the appointed members of the Board, at least two men and two women shall be non-residents of the town or city in which the examinations are to be held. All the appointed members shall be liberally paid for their services out of the school funds of the city or town.

The President of the Board of Education shall be the Chairman of the Board of Examiners. The Board shall select a clerk not one of their own members, and the Board of Education shall pay

the clerk for his or her whole time, or as much thereof as the Board may require.

The Board shall submit the candidates properly certified to be eligible to a strict physical examination, not omitting the slightest detail. A crooked toe, or a broken tooth shall count against the applicant. The applicants of both sexes must give evidence of strength and endurance. They shall have their lung capacity, eyesight, hearing and sense of touch tested. They will be required to run, jump, lift weights, "chin" themselves, etc., care being taken to limit the tests to such as will not be injurious to children or young people of the age of those examined. In preparing for this examination the candidates for the prizes should be warned that in the bodily tests, grace, agility and precision of movement will be marked higher than mere physical strength. The boys and girls shall have entirely separate physical examinations by examiners of their own sex, who may be aided by extra examiners (to be called in if required), and plenty of time shall be taken for a careful and complete examination in every case. One-half of the marks necessary to win the prize shall be awarded to the scholar having the highest aggregate of health marks for the entire course in the schools which give the prize, and one-half for the highest mark as the result of the final physical test. In case two or more competitors shall come out exactly even, additional tests may be required before the prize shall be assigned, or if in the judgment of the Board it shall be advisable to do so, the prize may be divided. At the conclusion of the physical examination, a report on each applicant shall be submitted to the full Board of Examiners, who shall be prepared to name the successful competitors. A majority vote of the entire Board shall determine the prize winners. In awarding the prizes, the decision of the Board shall be final, and not subject to appeal. But the reasons for selecting or rejecting any applicant shall be recorded and may be divulged to the applicant or to his or her parents or guardian upon request.

The teachers themselves should all be required to undergo a severe physical examination before their appointment to teach and at least annually thereafter. For schools in the vicinity of New York City the recently established Life Extension Institute would no doubt gladly undertake the periodical examination of the public school teachers, and would recommend to them any alterations in their mode of life that might be necessary to conserve their health and efficiency. So far as known, Dr. Greenwood's plan as carried out in Blackburn, England (of which city Dr. Greenwood was, and probably is yet, health commissioner, as we would call him in New York), for enlisting the teachers actively in the health work of the public schools has never been tried in America. He however gave it a good trial in the Blackburn Schools, and speaks highly of the result. The plan was essentially to make "the teachers our first line of defence," especially those teaching in the lower grades. He established a course of lectures on personal and school hygiene for the teachers and gave an examination at the conclusion of the course. I believe that only those who wished to do so took the examination. But those who passed it creditably received a certificate that they were competent to teach the rudiments of school and personal hygiene and were allowed an increase in their salaries. According to Dr. Greenwood, their work in this direction was

satisfactory to him and a great source of satisfaction to the teachers themselves. Their school tasks were more interesting, and their own and their scholars' health was benefited by this innovation and by the simple sanitary regulations which they inaugurated for their own and their scholar's benefit.

Of course this scheme will probably fail in execution unless a full time medical director is engaged in every school. He or she must be an enthusiast for the combined physical and mental education of children and must be a specialist in that line of work. He must have control of, and be responsible for, the hygiene of the school-houses and of the school-rooms. He must prevent over-crowding and over-heating of the rooms and over-working of the scholars. He must superintend the examinations of the latter called for in the foregoing plan and must be responsible for the proper filing and accuracy of the score cards, and must know that the children and their parents are given proper directions for conserving their health, and for correcting and remedying any remedial defects noted in any of the cases. He must also be competent to supervise and superintend all the athletic sports and exercises of the scholars and must be particularly alert to prevent any injury to any pupil for improper or too strenuous exercises. He must see that every teacher and scholar gets the requisite exercise, and must instruct the former in the simple rules of personal and school hygiene and must see that these are enforced. In short, he must have such authority as is now given in civilized countries to naval and military surgeons, whose word in hygienic and sanitary matters can be contravened only by the commander-in-chief.

There is no reason why this plan should not be put in practice in any city. It would soon be followed by a decided improvement in the present rather anemic character of much of the teaching in the lower grades. Teachers would learn to look upon their small pupils as human beings with minds and bodies to cultivate—and not merely as receptacles into which "learning" is to be introduced. Furthermore, the teachers would find themselves so much stronger and better in body and mind that they would begin to feel more respect for themselves, and a more vital interest in their work.

Naturally this plan will take time for its development, and will doubtless meet with considerable opposition. Yet, I believe that it, or some modification of it, will prove entirely workable.

By the adoption of these health and physical excellence prizes, by instructing the teachers in the elements of school hygiene, and by enlisting everyone in the health and physical well-being contest, a great step toward better general health conditions will have been taken. Everybody interested in the school will be perforce drawn into the movement. The parents could scarcely fail to be deeply interested. Small leaflets should be printed and distributed throughout the town at the beginning and the close of each school year, calling attention to the prizes and the rules of the contest, and the child's monthly health card should be in every case transmitted to the parent promptly and attention called to any remedial defects in the child's health or habits. Health lectures to parents, with special reference to the winning of the health prizes, should be instituted and given by the school medical inspectors at least monthly through the school year.

The expense of the movement need not be great.

Even if it were, the reward in the greatly increased interest in everything connected with health, hygiene and the bringing up of children would be of incalculable benefit to the schools, and to the community at large. If it did increase the taxes somewhat, the resulting benefit would be so obvious that no thoughtful person would think of finding fault with the scheme. The extra expense would be saved to the State many times over, by the resulting decrease in criminals, degenerates and imbeciles, and by the development of a higher and finer and more efficient average citizen and voter.

42 CHURCH STREET.

THE METHOD OF TRANSFUSION OF BLOOD TREATED WITH SODIUM CITRATE.

BY G. A. RUECK, M.D.,

NEW YORK.

THE method of transfusion of citrated blood was first published by Hustin¹ of Brussels in April, 1914. R. Weil² of New York read his article on "Sodium Citrate in the Transfusion of Blood" before the New York Academy of Medicine December 17, 1914, in which he made no mention of Hustin's work.

In January, 1915, R. Lewisohn³ of New York reported on a new method of blood transfusion, claiming the transfusion of blood treated with sodium citrate as his invention, but giving some credit to Hustin and Weil.

I myself⁴ have claimed priority in an article in the MEDICAL RECORD, February 27, 1915, and at the meeting of the Bronx County Medical Association, March 17, 1915.

I owe it to myself and to the profession to recapitulate the reasons for my claim and to publish this paper as a continuation of my preliminary report. The impetus to my experiments was given by a case of purpura hæmorrhagica in a woman referred to me December 12, 1913, by Dr. Clarence H. Smith. I treated this patient with hypodermic injections of human blood serum obtained from her husband and some male friends. December 31, 1913, and January 2, 1914, she received each time a transfusion of one quart of her mother's blood by Dr. F. L. Lindeman. His method, which is a modification of Von Ziemssen's method, made a great impression upon me, but it seemed to me beyond the reach of the general practitioner on account of its difficult technique and great expense.

Since 1912 I had used in my work as assistant pathologist and bacteriologist to St. Francis Hospital a 2 per cent. solution of sodium citrate to keep the red blood cells in their normal condition and to prevent coagulation of the sheep's blood which I got from the slaughter house for the Wassermann test. From my experience with this I conceived the idea of keeping the blood of a human donor liquid by means of a sodium citrate solution and to inject this mixture intravenously into a recipient. My experiments were the following:

EXPERIMENT I.—January 5, 1914. A gray female rabbit, weighing 2,053 grams and lying head downward on an inclined warming stage devised by me was bled from the post-auricular vein, 40 c.c. of its blood being collected in 10 c.c. of normal saline solution to which 2 per cent. of sodium citrate had been added. This blood was kept in the ice box. Then the jugular vein was resected. A small cannula connected by means of rubber tubing to a glass funnel tube was introduced into the jugu-

lar vein. The rabbit was now in a horizontal position on the warming stage. Into the slightly raised funnel tube 40 c.c. of sodium citrate blood of another rabbit was poured. This second rabbit, "the donor," had been killed 48 hours ago. Its blood had been kept in the ice box 48 hours and was warmed on a water bath to $37\frac{1}{2}^{\circ}$ C. before the transfusion was started. The rabbit died 6 days after the transfusion.

EXPERIMENT II.—January 6, 1914. A fox colored female rabbit, weighing 2,038 grams was bled from the post-auricular vein, 40 c.c. of its blood being collected in 10 c.c. of a normal saline solution containing 2 per cent. sodium citrate and was kept in the ice box for later use. Then the rabbit received a transfusion into the jugular vein of 40 c.c. of the sodium citrate blood obtained from rabbit No. I which had been in the ice box for 24 hours. The rabbit lived.

EXPERIMENT III.—January 7, 1914. A gray male rabbit weighing 1,850 grams, was put on the warming stage, and bled from the left post-auricular vein, 40 c.c. of its blood being collected in 10 c.c. of 2 per cent. sodium citrate in normal saline solution. Then the rabbit received into the right post-auricular vein by means of a large syringe an injection of 30 c.c. of blood obtained from rabbit II which had been kept in the ice box 18 hours. The rabbit lived. These experiments were encouraging.

Rabbits are sensitive animals, and when I saw they could be transfused with a large quantity of blood taken from another member of the same species and treated with sodium citrate I was sure that the same operation could be done on the human being. This fact I had determined through my animal experiments in January, 1914. I related my findings to members of the medical and surgical staff of St. Francis Hospital in January and spring of 1914; that is to say, before any publication of the sodium citrate method was made, and that is the reason why I claim priority for my work. If, however, the priority of work is only determined by the date on which an article appears in a medical journal, or by the date on which an article is received for publication or presented to a medical society keeping a record of its proceedings, the priority of the method of transfusion of blood treated with sodium citrate belongs only to Hustin of Brussels, who injected into dogs and into one man homogeneous blood treated with a solution of glucose and sodium citrate.

This method of transfusion of citrated blood is still in its infancy and its value must be demonstrated repeatedly through the report of cases treated by it in order to improve the method if necessary and to make its application general in whatever cases it is indicated. That is the reason for the report of the following cases and of the method used by me:

CASE I.—*Septicemia Complicating Acute Otitis Media in a Seventeen Months Old Child.* This case was reported upon, from the standpoint of an otologist, by Dr. C. H. Smith⁵ to the Bronx County Medical Society, October 22, 1915. Frank R., 17 months old, bottle fed, had been ill since May 22, 1915, with influenza, bronchopneumonia, tonsillitis, and double acute otitis media. A myringotomy on each ear had been performed on May 28, since which time the discharge from the ears had steadily diminished. The great toe of his right foot showed an abscess on June 1. On June 11, an abscess formed on the outer aspect of the left elbow. The temperature between May 27 and June 16 varied from 101° to 105° F. June 16 the temperature was 103° F., the pulse 148 and hardly perceptible, the respiration 68, and the child looked extremely ill. The child

was admitted to the Bronx Eye and Ear Infirmary and June 17, a simple mastoid operation was performed on the left side by Dr. C. H. Smith. The mastoid showed "no pathological changes." The abscess over the left elbow was opened and drained. The child had a septic temperature and over a dozen superficial abscesses in various parts of the body during the next couple days. During a second operation the left sigmoid sinus was exposed and incised and a large organized blood clot with flakes of pus throughout was found and curetted out. The clot extended into the lateral sinus and was curetted out for a distance of $2\frac{1}{2}$ inches. No hemorrhage occurred. The condition of the child became desperate and the operation was discontinued. The next day the left internal jugular vein was exposed and ligated above the facial branch, and several enlarged and infected glands were removed at the same time. June 20, 1915, I was called by Dr. Smith to do a blood transfusion on the patient. I found the little boy awake, but listless. He was very pale and had a septic appearance and odor. His pulse was imperceptible and his respiration rapid and shallow. The child was, according to my opinion, in a hopeless condition and a blood transfusion at such a late date seemed to me useless. Dr. Smith acknowledged too that there was no hope for the boy unless a miracle might save him and that this miracle might be brought about through a transfusion of blood. I collected 200 c.c. of the blood of the child's father into an Erlenmeyer flask containing 50 c.c. of N. saline solution and 1 per cent. sodium citrate and mixed it thoroughly. Then I resected the right cephalic vein of the boy and transfused him with 200 c.c. of the medicated blood. The pulse improved during and after the transfusion, the red color returned to his lips and cheeks, his respiration became slow and quiet and he grabbed eagerly for the bottle with milk and oatmeal jelly which the nurse brought him. After the blood transfusion he slept 7 hours and after his sleep he took 6 to 8 ounces of milk regularly every 3 hours. His condition was improving continuously. June 22 I gave him a second transfusion of 220 c.c. of citrated blood from the father into the same vein. The little boy got well and I ascribe his recovery entirely to the transfusion.

CASE II.—Lillian D., 24 years old, single, born in U. S., of Irish parents, clerk. Used to sleep in one bed with a sister who suffered with pulmonary tuberculosis. Diagnosis of her family physician was: Tuberculous ulcers of ileum near cecum, causing intestinal hemorrhage. After having treated the patient for some time with hypodermic injections of horse serum, Dr. F. called me July 10, 1915, to do a blood transfusion on this patient. He thought the patient would not live longer than six hours. She had lost 15 pounds in weight within two weeks. On July 10 the stools were tarry. The temperature was normal, the pulse 150, the respiration 40 to 50. She was very anemic, had air hunger, nausea, several attacks of syncope, and a slight pain in the abdomen, especially in the region of the ileocecal valve.

I drew from a 29 year old brother of the patient 750 c.c. and from a 20 year old brother 400 c.c. of blood, mixed each blood separately with a solution of 1 per cent. sodium citrate and 0.4 per cent. sodium chloride in distilled water in the proportion of 4 parts of blood to 1 part of solution. Into the resected right median basilic vein of the patient I injected in all 1,150 c.c. citrated blood. After the transfusion the pulse was 92 and regular, the temperature normal, the respirations quiet, deep, and at the rate of 22 per minute. The red color returned to cheeks and lips. She felt cold and had to be warmed by hot water bottles and warm blankets. The following night and the next 2 days her condition was excellent. The third day she felt again "sick in her stomach" and looked pale. It was planned to give a second blood transfusion in the morning of the fourth day, but before this operation could be performed the patient had a profuse hemorrhage from the bowels and died.

This case illustrates that a blood transfusion is the best means of arresting intestinal hemorrhage and that it should be repeated early if symptoms of hemorrhage reappear, as there is hope that the hemorrhage might be arrested if the lesion is not too extensive.

CASE III.—Emilie K., 16 years old, born in U. S., of German descent, single, a shipping clerk. She had whooping cough at 3, diphtheria at 6, measles at 3 and

7, tonsillitis every year, bronchitis at 7. Menstruation began at 14½, regular and normal. For the last 3 weeks patient has had pain in the throat on swallowing, especially in the morning, and a frontal, dull, continuous headache lasting all day and occurring once or twice a week. Appetite and sleep good. Patient is anemic with flabby muscles. Heart and lungs negative. Tonsils fibrous, hard. Adenoids present. She weighs 108 lbs. Hemoglobin and coagulation time of the blood were not determined.

July 27, 1915, at 9 o'clock A.M., under general anesthesia in my office, resection of both tonsils by the snare method and adenectomy were performed. Duration of anesthesia and operation 30 minutes. The patient seemed to be in a good condition after the operation, but there was a constant oozing of blood from the denuded surfaces. My attention was called to this by the second vomitus of blood which was rather abundant. Towels saturated with ice-cold water were applied to face and neck. Gauze saturated with adrenalin chloride, 1:1000 sol., was pressed continuously with two sponge-holders against both tonsillar beds. The bleeding stopped for only about half an hour. The bleeding from the roof of the pharynx was also alarming and could not be controlled by a gauze packing held in position by heavy silk strands which were pulled through the nares by means of a catheter. The pulse was at noon 102, at 3 P.M. 114, at 4 P.M. 120 and at 5 p. m. 130. At this time the pulse was very weak and hardly perceptible. The face was ghastly pale and the eyes glassy. The patient got drowsy, could not hear well, and was nauseated. The bleeding became more profuse. The vomitus (blood and gastric juice) measured in all nearly 2 quarts. The patient was now in a most dangerous condition. The last resort to save the girl seemed to me a blood transfusion and the mother, who had watched all my endeavors to control the hemorrhage, was willing to give her own blood for her daughter. I collected of the mother's blood 350 c.c. into each of 2 Erlenmeyer flasks containing each 100 c.c. of a 2 per cent. sodium citrate solution. Into the resected left basilic vein of the patient I injected these 900 c.c. of citrated maternal blood and in addition 225 c.c. of pure 2 per cent. sodium citrate solution. During the process of transfusion the patient's cheeks and lips turned gradually red, the pulse became slower, 104 per minute, was regular and of good volume and tension; *the bleeding stopped*. After the transfusion was completed the patient "felt fine" and walked without help to her bed. There was no bleeding during the night and no hematuria. At 8 o'clock the next morning the pulse was 100, the temperature normal, the respiration 20. The patient ate a hearty breakfast and went home with her mother. September 17, 1915. Patient weighed 114 pounds. Her mucous membranes looked normal, the muscular tone had wonderfully improved and the girl was well. January 20, 1916, patient weighed 117 pounds; March 19, 125 pounds.

CASE IV.—Mrs. B. W. J., 25 years old, German, in U. S. 10 years, married. Family history negative. She had scarlatina and diphtheria at 7; measles, whooping cough, and mumps at 4, a second attack of mumps lasting two months at 22. Three attacks of sore throat in 1909 and 1910, each attack lasting 10 to 14 days. Peritonsillar abscess in 1909. May, 1915, acute purulent otitis media; myringotomy; duration one week. Seven attacks of appendicitis between the ages of 9 and 14. The seventh attack was very severe and was complicated by a local peritonitis; yet there was no operation performed and the patient made apparently a complete recovery. Menstruation began at 15½ and was always normal when present. The woman had had 3 pregnancies with 2 normal labors and 1 abortion in the third month. First child died at the age of 7 weeks; second child living and well and 14 months old.

On August 14, 1911, patient gave birth to her first child. A few days after her confinement she began to have an attack of hay-fever which lasted until the first week in October. It was at first like a cold in her head. She sneezed frequently and had sore and itching eyes. The eyelids were swollen in the morning. Three weeks after the onset of this illness her throat began to be dry and hoarse. She had a heavy feeling in the chest. Breathing became difficult and was accompanied by a wheezing and rattling in the upper part of the chest. Quite often she had to gasp for breath, to sit down when outdoors or to run to the open window when indoors. In the middle of September she started to

cough and to expectorate much mucus, which sometimes was blood-streaked. The cough lasted until October. It seemed to be the finishing up of the hay-fever and was the worst part of it. The coughing spells lasted 10 to 15 minutes with about 5 minutes interval. The nose was always clogged up and the sleep was disturbed through the cough. Patient had chills and fever and a cold perspiration. The tongue was dry and swollen. There was loss of taste and appetite with loss of weight and strength. Patient lived on kumys, zoolak, milk and raw eggs. In 1912 the attack of hay-fever lasted from August 14 to October 1. Patient was on an ocean yacht. Every 1 to 2 weeks she went ashore for 2 to 3 days. When on land she had a bad attack of hay-fever which gradually improved after returning to the yacht. The year 1913 was the worst of all. The patient was in Spring Lake. Her attack of hay-fever lasted from the middle of August until the frost came in November. Next to the patient's cottage was a field of golden rod. The fever became most severe when the golden rod began to blossom. Then the field was mowed down, but the hay-fever kept on just the same. Four doctors in town and one doctor in New York City tried their art on the patient without much success. In 1914 the patient was in Belle Harbor from June 6 to Labor Day and afterwards in New York City. The attack of hay-fever lasted from August 15 to October 15. The cough started in the middle of September, lasted 4 weeks and was very severe. In 1915 the patient stayed in New York City. The hay-fever started August 20 and cough and asthma were very severe from the start. Her chest was a regular music box. She did not respond to menthol sprays, belladonna vapors, hot baths and a regulated diet, and was anemic.

September 9, 1915, I performed a blood transfusion on the patient in my office and was assisted by Dr. M. B. S. The patient was so nervous that I had to apply general anesthesia in order to introduce the needle. I injected 500 c.c. of blood from her sister mixed with a 2 per cent. sodium citrate solution into the median cephalic vein of her right arm. She stayed in my house and coughed much during the night. The windows were open and the west wind blowing over fields of golden rod produced severe attacks of asthma. September 10 at 2 o'clock A. M., the patient received ½ gr. of codeine phosphate hypodermically and slept until 6 A. M. Then she had another coughing spell. She received a second dose of ½ gr. of codeine phosphate and 1/100 gr. of atropine sulphate. In the afternoon, the chest was perfectly clear from râles. In the evening she ate a heavy beefsteak supper and felt better after it. On September 11, there was no cough except one slight attack in the afternoon. The urine was dark in the morning and light and clear in the afternoon. The chest was perfectly clear from rattles and the patient had no difficulty in breathing. She stayed in bed all day. The following day there was a few light coughing spells in the morning when getting up, none when in bed. Patient was free from cough and asthma afterwards.

I wished to do a second blood transfusion on this patient, but was unable to procure the necessary blood for her. Nevertheless the result of the transfusion was very gratifying. It arrested the hay-fever, and 24 hours after the transfusion the patient was practically cured, the disease having been shortened 5½ weeks to judge from the average duration of the previous attacks. This is, as far as I know, the first case of hay-fever successfully treated by this new method. I should have waited with its publication until next fall, until I had convinced myself that there would be no relapse, but this early report may stimulate others to apply this method next fall in their cases of hay-fever and may save many unfortunates a great deal of suffering. Therefore it is reported at this time.

Preparation of the Sodium Citrate Solution.

1.—In my animal experiments and in the transfusion of one man I used a normal saline solution containing 2 per cent. sodium citrate.

2.—In order to determine experimentally the least amount of sodium citrate necessary to keep the blood liquid I put into each of three ½ pint

fruit jars which I sent repeatedly to the slaughter house a certain quantity of a solution containing a certain percentage of sodium chloride and sodium citrate and had the jars filled with freshly drawn sheep's blood. I found that 1 part of a solution of 0.4 per cent. NaCl and 1 per cent. sodium citrate when mixed with 4 parts of blood would keep the blood liquid. I have used this solution in my first blood transfusions on man.

3.—In order to be safe and not to get a clot, even if the blood is not much shaken when drawn, I have returned to the 2 per cent. sodium citrate solution, omitting the sodium chloride entirely.

I have always several papers (at least 10), each containing 20 grams of sodium citrate, in my office and keep them in a glass-stoppered bottle. To prepare the sodium citrate solution I put the contents of one paper, 20 grams of sodium citrate, into a Florence flask of a capacity of 1000 c.c. and fill the body of the flask with distilled water, shaking the flask well when half filled and again when completely filled. Then I divide the sodium citrate solution into Erlenmeyer flasks. Into each flask I pour of the sodium citrate solution $\frac{1}{5}$ of the capacity of the flask. Into an Erlenmeyer flask of a capacity of 100 c.c. I pour 20 c.c. of the sodium citrate solution; into one of 250 c.c. I pour 50 c.c. of the solution; and into one of 500 c.c. I pour 100 c.c. of the solution. The Erlenmeyer flasks containing the sodium citrate solution are closed by cotton stoppers and sterilized in an autoclave at 15 lb. pressure for 30 minutes, or in an Arnold sterilizer on 3 successive days, each time for 30 minutes. I have always 2 or 3 extra Florence flasks with a sterile 2 per cent. sodium citrate solution ready for emergency.

Method of Taking the Blood.—The arm of the donor is gently massaged upwards at the place where the selected vein, usually the median basilic or the median cephalic vein, is situated. Through massage the veins become more prominent. Then the arm is painted with tincture of iodine. After 5 minutes the tincture of iodine stain is removed by a mixture of 3 parts of ethyl alcohol and 1 part of strong ammonia water. A tourniquet is applied to the arm, 4 to 5 inches above the place where the vein shall be tapped. It stays on as long as the blood is drawn. I use a small trochar (gauge $12\frac{1}{2}$) instead of a needle in order to shorten the process of taking the blood and in order to avoid too long a shaking of the blood in the sodium citrate solution, which procedure would be necessary in case a small needle or cannula would be used. I select the size of the Erlenmeyer flasks containing sodium citrate solution according to the amount of blood I am going to take. Suppose I need 200 c.c. of citrated blood for a transfusion, then I use 2 to 3 Erlenmeyer flasks of a capacity of 100 c.c. In case of hemorrhage, when I expect to transfuse 1,000 c.c., I collect the blood into 2 flasks, each of 500 c.c. and if possible into a third one of 250 c.c. capacity. The free end of the trochar is held into the mouth of the flask. The flask is constantly shaken in order to bring all the blood into contact with the sodium citrate solution and to avoid its coagulation. It is kept on a slant as long as the blood flows into it in order to avoid the falling of bacteria into the flask from above. There is no danger that bacteria will enter the mouth of the flask from the direction of the trochar, as the blood in the flask is rising and driving the air out of the flask. There is a stream of air out of but not into

the flask. Since no air enters the flask no dust and bacteria can be carried into it by a current of air. As soon as the flask is filled with blood it is replaced by an empty one. It is stoppered and shaken from side to side, not up and down. The flasks with the blood are kept at room temperature for immediate use or put into the ice box when the transfusion is going to be done later, in which case the citrated blood has to be warmed to 37.5° C. before the transfusion.

It is essential to be sure that there is no clot in the blood mixture. Should there be a small clot, it must be removed from the blood mixture by decanting the blood into an empty flask. If a large clot forms, as it happened to me once with a 250 c.c. Erlenmeyer flask when I collected blood into a 1 per cent. sodium citrate and 0.4 per cent. sodium chloride solution which was not sufficiently shaken by the assisting nurse, the flask of blood must be discarded.

The Recipient.—It is best to keep the patient or recipient in another room when the blood is taken from the donor in order to save the patient from excitement and shock. He is in bed or on the operating table and in a recumbent position. The arm is prepared like that of the donor. A tourniquet is applied to the arm before the needle is introduced.

The apparatus which I use for transfusion is a Kaliski apparatus. One of its cylinders is filled with citrated blood, the other with 2 per cent. sodium citrate water. The sodium citrate water is used for testing the working of the apparatus and for driving the blood contained in the rubber tubes into the vein at the end of the transfusion. The open ends of the cylinders are covered with pieces of sterile gauze. A Kaliski needle is introduced into the vein and connected with the tubing of the apparatus as soon as it is shown by the flow of blood from the needle that the needle is correctly introduced into the vein. In case the vein is difficult to find through the skin I make after one unsuccessful attempt to puncture it a small incision into the arm, lay the vein bare, put an artery clamp under it, push the needle into the vein just where it is supported by the artery clamp, connect the properly introduced needle with the tubing of the apparatus and have the tourniquet removed.

The blood flows slowly into the vein, the graduation of the cylinder showing the amount. The transfusion has to be discontinued (1) when the patient tells you that he "feels to be full," or (2) when in the absence of this remark the patient's pulse returns to its normal rate, volume, and tension.

The transfusion being completed, the needle is extracted and the arm bandaged. In case of resection of the vein the needle is withdrawn from the vein, the supporting clamp removed, the skin sutured and the arm bandaged. The patient stays in bed, is covered warm and receives a warming bottle to his feet.

The addition of sodium citrate to the blood seems to be objectionable to many otherwise progressive physicians. "What is the use of introducing into the blood system a mixture of sodium citrate solution and blood when we want pure blood?" they say. The answer to that is, "If you can do it, transfuse pure blood, if you cannot, transfuse your patient with citrated blood." The sodium citrate method is in my estimation not an inferior substitute to the cannula method but is equal to it in its results and superior to it in the

readiness with which it can be applied. The sodium citrate solution mixed with human blood in the proportion of 1:4 or even 1:3, does not bring about an alteration of the red and white cells and of the serum. The protecting forces of the blood are not diminished. Of course changes occur in the mixture of sodium citrate solution and blood if it is kept too long in the ice box (several days). I prefer to perform the transfusion as soon as possible after the blood has been drawn, avoiding timid haste.

For a second and third transfusion I prefer to draw and prepare the blood freshly. The quantity of sodium citrate used for transfusion is not large enough to be toxic. The danger of contamination is nil if the same precautions are taken which a bacteriologist has to observe when he makes blood cultures. The temporary polyuria occurring in some patients after the transfusion with citrated blood is in my opinion no objectionable symptom.

The determination of hemoglobin before the transfusion and at certain intervals after it is important in chronic anemias, demonstrating a gradual improvement or, after an improvement, a return to the old condition, being thus an indicator for the repetition of a transfusion. It can be omitted in emergency cases and in cases of acute infections.

The Donor.—I have used the nearest relatives for giving the blood for my transfusions, the father giving the blood to the son, the brothers to the sister, the mother to the daughter, the sister to the sister. These donors were healthy individuals. There was no time for making tests for hemolysis, agglutination and Wassermann reaction and for examining the blood for malaria. The results were nevertheless good.

Naturally, when strangers are used as donors, they should be healthy and vigorous individuals and their blood should be examined for malaria and tested as to its compatibility with that of the recipient. The Wassermann test is very important and should be made with the donor's blood if there is any doubt in case of relatives. It should always be made in case the donor is a stranger.

Conclusion.—A physician should try to acquire the technique of the Von Ziemssen indirect syringe cannula method as modified by Lindeman and others and apply it when possible and indicated, especially when he intends to make a specialty of blood transfusion.

For the general practitioner, however, the sodium citrate method, being simpler, is the method of choice.

Medical Preparedness in War.—Lieutenant-Colonel Fisher gives as an example of this the fact that when a division was ordered to concentrate at San Antonio in 1911, the full equipment for 20,000 men was in the railroad yards at San Antonio within less than eight days after the instructions for the shipment were telegraphed from the surgeon general's office.—*The Military Surgeon*.

POLYCYTHEMIA VERA.

By G. A. FRIEDMAN, M.D.,

NEW YORK.

ATTENDING PHYSICIAN IN DIGESTIVE DISEASES, VANDERBILT CLINIC; GASTROENTEROLOGIST, GOUVERNEUR HOSPITAL.

POLYCYTHEMIA or erythremia is a peculiar and a distinctive symptom-complex which first became known in 1892 (Vaquez¹). However, the importance of this condition was not realized until 1903, when Osler² collected and summarized the details of nine cases.

Polycythemia vera, commonly called Vaquez-Osler's disease, is marked by a persistent increase of erythrocytes, of an increased percentage of hemoglobin, of splenomegaly, and of redness or cyanosis of the face. The affection is further characterized by headache, vertigo, attacks of vomiting, and slight albuminuria with casts. Blood may occasionally be present in the sputum, vomitus, or stools. The malady occurs in both sexes and shows its preference for individuals in the fifth decade of life.

The average duration of the illness according to Osler³ is from six to eight years. The disease does not respond to therapeutic measures, although it is said by some that good temporary results have been obtained by the application of Roentgen rays to the spleen and to the long bones.

There are in all about twenty-three necropsy reports. In the majority of these cases no deviation from the normal histology of the spleen could be detected; in three cases, however, splenic tuberculosis was found, and in two cases vascularity and congestion of the spleen. But the most constant findings at these autopsies were, first, true plethora (since all parts of the body were engorged), and, secondly, the transformation of bone marrow from the yellow fatty to the vivid purple variety, with erythroblastic and leucoblastic hyperplasia. It is believed by Widal (Osler⁴) that through the loss of splenic function the bone marrow becomes abnormally stimulated so that hyperplasia and polycythemia result.

Notwithstanding the fact that the disease in question in its typical form is characterized by a definite group of findings: polycythemia, splenic enlargement, and cyanosis of the face, yet the affection, as I have become convinced lately, is not recognized by the practitioner at large. It seems to me, therefore, that the report of an additional case may be of value.

Mrs. D. M., Russian Jewess, forty-six, was first seen by me April 22, 1915, at the Vanderbilt Clinic, to which she was referred by Dr. Reigrod.

Past History: Denies ordinary diseases of childhood, but definitely remembers having had typhoid fever when very young. Since then has been in perfect health until about four years ago when she fell from a wagon and struck her left side. Immediately after the accident and for several weeks thereafter the patient experienced pain in left lumbar region. When the pain disappeared, she became extremely nervous and then sought the advice of a physician. He curetted the uterus, though she had not suffered at any time from uterine hemorrhages or painful menstruation. Patient has three healthy children. Never had any miscarriages and denies syphilis by name and symptoms.

On the third month following the operation she began to complain of extreme weakness, palpitation of the heart, and dizziness, these symptoms being especially marked during her menstrual flow so that she was compelled to stay in bed during her periods. But the menstruation itself was characterized neither by a profuse bloody discharge nor by pain. During the menses her hands would become blue and if she attempted to sit she felt as if "her heart were going to pieces."

Family history is negative. Appetite good. Bowels somewhat constipated. She uses tea and coffee moderately, but takes no liquors. Micturition normal.

Present illness: The above symptoms have recently become aggravated, but the patient noticed several months ago that the dizziness and palpitation of the heart were relieved temporarily by partaking of food. This relief, which follows almost immediately, has caused an increase in her intake of food, though her appetite has actually decreased. During the last few months she has become obstinately constipated. Her face becomes frequently flushed and especially so when she has not had a bowel movement for several days. Vomits occasionally but has never noticed blood in the vomitus. Lately has had continuous frontal and occipital headaches, which she could not relieve by any measure. She also has a constant sensation of pressure in the left hypochondrium and a sticking pain in the lower extremities. Has chilly sensations, but no fever or sweats. She has lost 38 pounds during past four years.

Findings on physical examination: Patient is well developed and well nourished. The face, especially the nose and cheeks, is of a brick red color. The lips are decidedly blue. The skin over the rest of the body is dry. The pharynx is red. Hands and feet are cold. Superficial lymphnodes are not palpable. Eyes normal, except for a slight dilatation of retinal veins. Lungs normal. Heart sounds clear, no dilatation to right or left. Pulse, 84. Blood pressure, 130 mm.hg. Temperature, 98.8° F. Liver border not palpable. Spleen palpable and extends 4 inches below the costal margin, reaching almost the level of the navel; its surface is smooth and not tender. The uterus is slightly retroverted, adnexa normal; no leucorrhea. Urine examined repeatedly showed the same findings; namely, traces of albumin, excess in indican; sugar, bile, urobilin absent. In the sediment there are a few hyaline casts.

Gastric analysis one hour after test breakfast: 60c.c. of well digested food obtained; free MCl, 54; total acidity, 82. No residue of food on morning after test supper.

Date	Hemoglobin, Per Cent	Erythrocytes	Leucocytes	Polynuclear, Per Cent	Lymphocytes, Per Cent	Large Mononuclear, Per Cent	Eosinophiles, Per Cent	Basophiles, Per Cent	Transitional Lymphocytes, Per Cent
April 23	134	9,410,000	17,000	84	10	1	2	1.5	1.5
April 24....	138	10,240,000	23,000	85.5	10.5	0.5	2	1.0	1.5
May 29	135	10,400,000	19,000	88	8	0.5	1	1	1.5

No abnormal cells, no *Plasmodium malarix*. The determination of hemoglobin was made by the Sahli method. For blood films the Jenner stain was used. In the differentiation of the leucocytes 400 cells were counted. The relative increase of polymorphonuclears was marked even on the day when the absolute number of leucocytes was normal.

Diagnosis: The persistent findings of polycythemia, of splenic enlargement, and of marked redness of the face with cyanosis of the lips made the diagnosis of Vaquez-Osler's disease certain.

Treatment: Treatment was begun with arsenic (Turck.), but was soon discontinued for patient began to complain of an increase in her dizziness. Thyroid tablets (0.1) (Münzer⁶) twice daily were stopped after five days on account of vertigo, an increase in the palpitation of heart, and restlessness. Patient refused to enter a hospital and therefore venesection could not be tried. Carlsbad salt before breakfast has relieved the patient somewhat, perhaps by counteracting the hyperchlorhydria. In May and in June x-ray treatment was given (Dr. S. Hirsch).

The following table gives the results of blood examinations made while under x-ray treatment.

Date	Hemoglobin, Per Cent	Erythrocytes	Leucocytes	Polynuclear, Per Cent	Lymphocytes, Per Cent	Large Mononuclear, Per Cent	Eosinophiles, Per Cent	Basophiles, Per Cent	Transitional, Per Cent
May 16	120	10,000,000	16,200	90.5	6	0	2	0	1.5
May 27.....	118	9,880,000	13,000	89.5	12.5	0.5	1.5	0	1
June 25.....	124	10,800,000	13,200	86	10	0.5	1	0.5	2

From the later bloodfindings it is evident that there was no change during the application of Roentgen rays. However, the determination of the hemoglobin showed lower values. The spleen did not diminish in size. But one must admit that the general condition has markedly improved: dizziness and vertigo have almost entirely disappeared and the appetite has somewhat improved. From the end of July no further observations were made as the patient did not report.

Aldrich and Crumer⁶ tried x-ray treatment in one case with very good results. Lucas⁷ refers to two cases in which the application of Roentgen rays to the spleen was of benefit. In six other cases, however, this treatment, he points out, was unsuccessful.

It is not necessary for me to analyze the cases in the literature, as the paper of Engelbach and Brown⁸ contains an excellent bibliography on this subject up to 1906. Lucas in his monograph gives an analysis of 149 cases from 1892 to 1912. He rightly states that polycythemia vera is not by any means as uncommon as it was at first supposed.

The etiology is still unknown. There is a distinct history of trauma in this case. It will be remembered that the patient fell from a wagon and definitely dates the onset from this fall. Whether injury was an inciting factor or not is doubtful. Watson⁹ refers to two cases of polycythemia vera where trauma to the bones was present.

THE SIGNIFICANCE OF HEMORRHOIDS.

By ARNOLD H. MAY, M.D.,
BUFFALO, N. Y.

IN view of the modern conception of disease it is no longer feasible to look upon hemorrhoids as a local condition. Viewed from the prophylactic side of medicine, hemorrhoids must assume a more important position, as they are seen to be important factors in the etiology of disease. Ascribing this importance to them will tend to prevent a host of diseases for which they may be responsible.

A glance at the anatomy of the anorectal region will show the venous drainage to be accomplished by the superior hemorrhoidal vein, which is a branch of the inferior mesenteric vein, finally draining into the portal system, and by the middle and inferior hemorrhoidal veins which drain into the systemic circulation. Anatomically, then, the veins from this area drain into both the visceral and systemic circulation, thus bringing the liver into relationship with this area. The lymphatics of the rectum drain into the preaortic nodes.

Hemorrhoids are dilatations of the hemorrhoidal veins produced by a variety of causes. Anatomically they are divided into external and internal. They are covered by epithelium. Because of their position they are constantly subjected to irritation from advancing feces, and excoriation of epithelium may occur. Local hemorrhages are frequent, and through such factors a prolapse, thrombosis, infection, ulceration, or even gangrene may occur. Thus by this process vascular channels and the lymph spaces are opened, and in contact with more or less putrid feces may be the source of an infection.

In disease of the area, where there is much epithelial denudation as where ulceration or gangrene has occurred, the bacteria present may gain entrance into either the visceral or the systemic venous circulation. The bacteria present in this region are numerous; even more abundant here than in the buccal cavity, and in as great variety. Diseases of the oral cavity such as alveolar abscess, pyorrhea alveolaris, as well as tonsillar disease have been looked upon as prolific sources of disease elsewhere, such as cardiac disease, etc. Similarly bacteria in the anorectal region, in diseased conditions of this area where the epithelial barriers are destroyed, and the resistance of the individual lowered, may reasonably, upon entrance to the system, excite a pathology characteristic of the specific infection. Especially is this possible in hemorrhoids when it is remembered that a depletion of the system often occurs by severe hemorrhages, giving rise to a secondary anemia, with a consequent diminution in resistance. It is manifest that feces in contact with abraded, bleeding surfaces presents the elements essential for possible infection. Animals inoculated with bacteria from the anal region, undergo the disease process characteristic of the specific infection. Autoinoculation in humans may occur in the same manner. Fistula in ano and other anorectal conditions have long been considered etiological factors in disease. Surgical interference in the former, when of tuberculous origin, may give rise to tuberculous infection or when already existing to an accentuation of the process. Frequency of infection following hemorrhoids must depend upon individual variations in resistance. Obviously many individuals suffering from hemorrhoids will not acquire a general infection, just as we see that cardiac disease will not invariably follow a tonsillar abscess.

What diseases then may owe their origin to hemorrhoids? Anatomically it has been shown a direct condition exists between the anorectal region and the liver. Particularly in the case of internal hemorrhoids injection may pass, when the superior hemorrhoidal radicles are affected, through the inferior mesenteric vein to the portal system, and hence to the liver. The organisms gaining entrance to the biliary system may excite inflammation of the biliary ducts, cholangitis; and the infected bile likewise in the gall bladder may produce a cholecystitis. Cholelithiasis may also occur, the bacteria acting as nuclei, or causing a lithogenous catarrh. Appendicitis, intestinal toxemia, or any primary intestinal lesion may operate in the same manner. Streptococci-staphylococci, pneumococci, colon and typhoid bacilli have been frequently found in the bile. The typhoid bacillus is a common source of biliary infection in typhoid fever. In fact the bile seems a peculiarly favorable habitat for microorganisms. The infected bile is discharged into the duodenum, and here may excite a duodenitis or an

ulcer. La Rocque believes that the bacteria responsible for duodenal ulcer reach the duodenum from some pathological area of the abdomen drained by the portal veins. Hemorrhoids may possibly be such a source. Again the organisms from this source reaching the systemic circulation may give rise to a variety of conditions dependent upon embolic phenomena. Endocarditis and its sequelæ are only one of the possibilities. Organisms from this area may, like organisms from the buccal cavity, be potent factors in disease production.

A recent case which illustrated the possibility of hemorrhoids playing an important rôle in the etiology of disease was presented by a female patient who suffered from hemorrhoids and at the same time was subject to periodic attacks of jaundice, fever, and gastric symptoms. Since obtaining relief from the hemorrhoids she has had but one mild gastric attack. An interrelationship between the two conditions seems very possible. In the campaign of prophylaxis in medicine the same significance should be attached to foci of disease in the anal and rectal regions as to those in the buccal cavity. Treatment of hemorrhoids should be undertaken with a view to ameliorating and curing the local condition, and eradicating a possible source of severe infection. The physician then must understand that in combating them he is not only caring for a more or less severe local manifestation, but is also obliterating a nidus, the possible source of severe infection.

177 WALNUT STREET

DILATED HEART AS A SIGN OF EARLY APICAL PULMONARY TUBERCULOSIS.

BY MAX GROSSMAN, M.D.,

BROOKLYN, N. Y.

PULMONARY tuberculosis, long before physical signs of same appear in lungs, often shows its effect on the heart. One of the earliest conditions noticed is pulmonic accentuation. This means that the pulmonic second sound is louder at the second left pulmonic interspace than at the second right aortic interspace. This is abnormal in adults, and when obtained is of value, of course, in connection with other signs.

The writer, however, has observed a sign which it seems to him has not been emphasized, and which it would appear in his experience to be of great value, taken in conjunction with other signs, in the diagnosis of early apical pulmonary tuberculosis.

One of the earliest effects of the tubercle bacilli, long before physical signs may show in the apices, is dilatation of the heart. Even patients themselves in incipient tuberculosis very often do not complain of cough, loss of weight, etc., but the first thing noticed is "pain under the heart," a general weakness of the precordium.

Dr. Robert Abrahams showed convincingly some time ago that acromial breathing, on auscultation of the acromial processes of the clavicles, will show early tuberculous signs long before they appear in the lungs. The writer has noticed, however, that slight dilatation of the heart, diffuseness of the apex beat seen or felt at the fifth left intercostal interspace appears very often simultaneously with, or even precedes, the earliest physical signs of incipient pulmonary tuberculosis.

It would seem, therefore, that in incipient cases of apical pulmonary tuberculosis, which in the adult number probably about 499 out of every 500 cases

observed, one of the earliest effects of the tubercle bacilli is its effect on the heart. Of course, it may be argued that the reason the pulmonary tuberculosis follows dilated heart is that dilated heart might show a general run-down condition and tuberculosis would naturally follow on this weakened physical condition. The writer has, however, noticed in apparently strong, able-bodied individuals, where there was as yet no sign of the general physical condition being below par, that one of the earliest signs, in many cases long before the lungs showed the onset of apical pulmonary tuberculosis, was a diffuseness of the apex beat, meaning commencing dilatation of the heart.

This dilatation of the heart may, under proper hygienic and tonic treatment, become so improved as to be almost absent in arrested first stage conditions. Here it would show the tubercle bacilli were not active or had been gotten under the control. But no sooner does the tuberculous process become active again than dilatation of the heart becomes apparent once more, and continues throughout the case.

124 LEE AVENUE.

Medicolegal Notes.

Liability for Direction to Employees Not to Employ Designated Physician.—A railway employee's beneficial association organized to furnish medical and surgical aid to its members retained physicians at various points, and its rules required members needing medical or surgical aid at the association's expense to call the nearest authorized physician, except that in sudden emergencies other services for first attention might be procured. Though any deficit in the funds of the association was made up by the railway company, it had a separate entity. Its president wrote the general superintendent of the railway, calling attention to the expense caused by the disposition of certain employees to call in a certain Dr. P., who was not one of the association's physicians. The superintendent wrote to division superintendents, stating the president's grievance, and said the practice mentioned might not be resorted to except in emergency cases. One of the division superintendents issued a circular quoting the association's rules and expressing the hope that it would not be necessary again to call attention to the embarrassment of the railway company and the association through failure to comply with instructions. He also verbally told a yardmaster that it was his desire to have the company physician called in all cases in preference to Dr. P. or any other doctor. By the yardmaster's direction the following notice was posted: "In case of accident to an employee where medical attention is needed at once, do not in any case call Dr. P. If company doctor cannot be located, order ambulance and have party sent to hospital." Dr. P. sued the railway, its general and division superintendents, the yardmaster and his assistant, alleging that the notice was maliciously intended to and did injure him in his business. It was held that, while the association could, under proper circumstances, have lawfully signified to its members by any proper means its indisposition to have any dealings whatever with the plaintiff, the notice was a departure from the president's letter and unauthorized by the association. The general superintendent and the division superintendent were not liable to the plaintiff, as what was written or said by them was within the range of the president's request and constituted no order to the yardmaster to go beyond what the rules of the association required. The yardmaster was liable, notwithstanding his alleged want of actual malice, as he was not directed to publish a notice that under no circumstances should Dr. P. be called. His action was wrongful and malice might be implied. The railway company was also liable, it being within the general scope of the yardmaster's employment to publish suitable notices to such of the company's employees as were under his direction, since, in permitting its channels to become the medium through which the association should speak to its employees, it undertook to answer for wrongs committed in that process. The plaintiff sued for the loss of such emergency practice, chargeable to the association as would have come to him but for the notice,

but his testimony touched only his entire activities among yard employees and no figures were given or circumstances stated from which it could be determined what portion of the whole loss came within the class of emergency cases for which liability was claimed. It was held that there was a failure of proof, and he could recover nominal damages only.—*Peek v. Northern Pac. Ry. Co.*, Montana Supreme Court, 152 Pac. 421.

Privileged Communications.—The Wisconsin statute of 1911, section 4075, as amended by Laws 1913, chapter 349, provides that no physician or surgeon shall be permitted to disclose information acquired by him in attending any patient in a professional capacity and which was necessary to enable him to prescribe for the patient or do any act for him as a surgeon. In an action for personal injuries sustained in a slight collision between two street cars, in one of which the plaintiff was a passenger, her evidence tended to show that she suffered from inguinal hernia resulting from the accident. The defendant called as a witness the physician who treated the plaintiff after the injury, and asked him whether he treated her for hernia and whether the plaintiff complained to him of hernia. It was held that the trial court properly refused to permit the physician to answer the questions. "If," the court said, "the questions propounded to the physician in the present case were answered either way, the statute would be set at naught. It was the physician's duty to treat the patient for whatever disease or infirmity the diagnosis of the case showed that she had. If, therefore, he answered that he treated her for hernia, the necessary inference of fact would be that the statements or symptoms of the patient or the physician's examination tended to show that she was suffering from hernia; if he answered that he did not treat her for hernia, the inference of fact must be that such statements, symptoms, or examination tended to show that she was not suffering from hernia, but from some other difficulty. In either case the effect would be to disclose a part of the information which the statute says shall not be disclosed."—*Dreyfus v. Milwaukee Electric Ry. & Light Co.*, Wisconsin Supreme Court, 154 N. W. 840.

Death Certificate as Evidence.—In an action against a fraternal benefit insurance association the death certificate of the physician who attended the deceased in her last illness, after stating that the death was caused by peritonitis, went on to state that the contributory cause thereof was abortion. It was held that that part of the certificate was not inadmissible as hearsay, but the remainder of the certificate, reading, "said by decedent to have been performed by Dr. —," was properly excluded, since a fair interpretation of the certificate was that the contributing cause of death was primarily within the knowledge of the physician, and was not hearsay.—*Gilchrist v. Mystic Workers of the World*, Michigan Supreme Court, 154 N. W. 575.

Waiver of Privileged Communications.—A plaintiff recovered judgment for \$8,000 damages and costs on account of a personal injury. He swore to the facts of the injury and his condition, and called physicians who had attended him, who swore minutely as to his condition. Some of them took, or assisted in taking, x-rays of the organs and parts of the body claimed to be injured. The testimony of the plaintiff's physicians put before the jury, with great minuteness and circumstance, his physical condition, especially at the time when he was at the Samaritan Hospital. The defendant called Dr. Harvie, a surgeon connected with the Samaritan Hospital, who had examined the plaintiff there at his request, and he was asked: "What did you find the man was suffering from?" The plaintiff objected, as incompetent and inadmissible under the New York Code. The objection was sustained, and the defendant excepted. The plaintiff put his person before the jury as a basis for damages, and had it described by his physicians, and the Appellate Division held that he thereby waived any privilege, not only of the physicians he called, but of other physicians, who examined him about the same time. It did not appear that Dr. Harvie made his examination at the same time that the other physicians made theirs, but it did not seem that that fact was controlling. The examination was at the same time the doctor was treating him for the same trouble. It seemed unfair that he could call certain of his physicians and refuse to permit others to testify on the ground of professional privilege. Judgment for the plaintiff was reversed and a new trial ordered.—*Dewey v. Cohoes & L. Bridge Co.*, 155 N. Y. Supp. 887.

MEDICAL RECORD.

New York, April 15, 1916.

PRACTICAL APPLICATIONS OF THE SCHICK REACTION.

OF all the immunological reactions that have been introduced in recent years the Schick reaction seems to have the broadest field for application and perhaps the greatest practical value as well. It will be remembered that the reaction consists in the intracutaneous injection of one-fiftieth of the minimum lethal dose for the guinea-pig of diphtheria toxin. A positive reaction consists of the appearance within twenty-four to forty-eight hours of an area of redness and slight infiltration about the point of injection. On fading this area shows superficial scaling and a persistent brownish pigmentation. The amount of fluid injected, as advised by Schick, was 0.1 c.c., but the Department of Health has preferred to recommend a dose of 0.2 c.c. in order to avoid the fairly severe local reactions which were occasionally seen after the use of the more concentrated fluid.

Zingher has recently published (*N. Y. State Jour. Med.*, 1916, XVI, 118) a report of some extensive investigations into the treatment and prophylaxis of diphtheria by means of the Schick test which have produced results so interesting that they demand mention in these columns. Schick showed that a negative reaction occurred in patients whose blood contained one-thirtieth of a unit of antitoxin per cubic centimeter and that this amount was sufficient to protect the individual against the development of the disease. A positive Schick test means diminished antitoxin content and therefore a susceptibility to diphtheria. Pseudo-reactions occur, but disappear more rapidly and never show the superficial scaling which is characteristic of the true reaction. In the first place Zingher found a tendency for members of one family to react in a similar fashion to the test, showing the presence, possibly of some hereditary factor. In tests devised to show the relative value of different methods for the administration of antitoxin he found that when given subcutaneously, twenty times the amount was needed to produce the same effect upon the reaction as was produced by intravenous injection. The duration of a passive immunity resulting from the injection of 1,000 units of antitoxin was found to vary between 21 and 25 days, as a rule, while a second injection given at the end of this period will protect for only five to eight days. He

was also able to detect a number of patients who suffered with mild tonsillar diphtheria and who recovered without antitoxin and yet who at all times gave a strongly positive Schick reaction. They evidently had developed no antitoxic immunity and must have recovered as a result of the development of a bactericidal immunity only. The author studied a large number of such cases and comes to the conclusion that diphtheria patients develop as a rule an antibacterial immunity, which is associated in only about one-third of the cases with an antitoxic immunity. Efforts to produce an active immunity by means of mixture of toxin and antitoxin were unsuccessful in about 75 per cent. of those patients who, at the outset, had no natural immunity. The use of vaccines of the Klebs-Loeffler bacillus was without favorable results.

From a study of over 1200 cases Zingher is convinced that the test is absolutely reliable in showing the presence or absence of antitoxic immunity and that a negative test indicates that the individual is protected, probably indefinitely, against the disease. The test is also of value in clearing up the diagnosis of clinically doubtful cases, since a negative reaction excludes diphtheria although the patient may still be a carrier. Carriers who give a positive reaction should be immunized before the institution of any operative procedures upon the nose or throat, since the operation may result in the breaking down of the local immunity which had protected them. Further, the use of the reaction will result in a great saving of antitoxin and avoid the needless sensitization of individuals already immune. Such broad scientific and practical applications are found in few other immunological procedures and justify the great popularity which this test already enjoys. The Department of Health, in whose laboratories and hospitals this work was done, has done everything in its power to further the use of the test and it is to be hoped that the general practitioner will heartily cooperate in their endeavors.

WOMEN AS MEDICAL MISSIONARIES.

THERE is a wide field for the employment of women as medical missionaries. In some lands into which missionaries go to look after the spiritual and physical welfare of the inhabitants men are not allowed to treat the native women medically. In India, for instance, the custom of a large part of the population forbids that men doctors should attend patients of the female sex. In consequence, disease is spread, and sickness and mortality are greater by far than would be the case were efficient medical services available. On the other hand, the services of female physicians are eagerly sought, and there is, therefore, almost unlimited scope for the exercise of their knowledge and skill in some of the Far Eastern countries. At the Conference on the Training of Medical Missionaries, held in New York on April 5 and 6, 1916, various phases of the matter were discussed. Among the papers read was one by Dr. Belle Allen on the preparation of women for medical mission work and how it should be differentiated, if at all, from that of men. This paper dealt with the subject matter in a very able way, and suggested in a particularly

clear manner the lines along which women medical students preparing for mission work should be trained. However, although, of course, the question of proper training is an all-important one and the paper contained very useful hints in this direction, the difficulty now is in procuring candidates. The demand is greater than the supply by far. Dr. Sanders, the secretary of the Board of Missionary Preparation, stated that a considerably smaller number of women enter medical schools to train as missionaries than ten years ago. This decrease in numbers is not due to the fact that female medical missionaries are not needed; they are needed more than ever before. It does not seem to be due to distaste for or indifference to the work. The life of a medical missionary undoubtedly appeals strongly to many earnest women; it appeals from the point of view of being of assistance spiritually and physically, and to a woman nothing exerts a stronger claim on her humanity and pity than of being a help to someone. The life of a medical missionary, too, offers something of adventure, an inducement of no mean value to the energetic self-respecting woman who often feels that her brains and capacity for work and for doing good have too little scope for exercise at home. It would seem as though numbers of young women would hail with enthusiasm the opportunity for launching on the career of a woman missionary.

The explanation of the inadequate supply of women medical missionary students appears to be found in the lack of opportunity. In the first place, many of the best medical schools in the country do not yet open their doors to women, and it must be borne in mind that those responsible for the management of the Medical Missionary Society in this country desire only those who have qualified in such schools. It is true that several of the best schools receive women students, and others expect in the near future to do the same, but the fact remains that the majority of the high standard medical schools of the country deny to women the right to study for a medical degree. There is yet another obstacle in the way of procuring an adequate supply of women medical missionaries, and that is the expense attached to the period of training. The women who are most likely to take up the career of medical missionaries and who are best fitted for the work are not plentifully endowed with this world's goods. They do not belong to the leisure class, but are born of workers who frequently have to strain every nerve to make both ends meet. By inheritance and environment they are workers and are of the stamp that would make ideal medical missionaries, if only opportunity came their way. The lack of money is the great stumbling block to the ambitions of many girls who are peculiarly well adapted by their heredity and bringing up to render service to God and man in the medical missionary field. Perhaps one or other of our multi-millionaire philanthropists will some day provide a fund sufficient to aid the passage of enough would-be women missionaries through a first class medical school, and thus solve a problem which is greatly exercising the minds of the directors and leaders of missionary enterprise.

POINTS ON PREPAREDNESS.

WHETHER we have a standing army of fifty thousand men or five million, whether our navy consists of a half a dozen prehistoric butter-boats or a vast fleet of the latest word in leviathans, it behooves us of the medical profession to turn our thoughts toward the duties which may reasonably be expected of us in case of war. There seems no doubt but that the majority of the physicians in his country would then find themselves facing a problem in which their previous experience would afford them little or no help. Since the late unpleasantness between the latitudinal sections of our country surgery has taken strides comparable only with the evolution of the stage coach into the aeroplane, and the general practitioner who confines his surgical efforts to circumcisions, ingrowing toe-nails, and the incision of abscesses would find himself on a terra incognita when dealing with the devastating effects of hand grenades.

One who wishes to obtain some idea of surgery in modern warfare would do well to read carefully the "Report on Medico-Military Aspects of the European War" by Surgeon A. M. Fauntleroy, U. S. N., to which we have referred before. Dr. Fauntleroy was sent by the Navy Department in April, 1915, to France to study and report on the medical aspects of the war; he served on the surgical service at the American Ambulance Hospital in Paris for two months and with Dr. Alexis Carrel he visited all the field hospitals in the regions between Compiègne and Soissons.

Dr. Fauntleroy's observations are too replete with important matter to lend themselves to any adequate abstract, but a few points may be quoted here. He was particularly impressed with the difficult problem presented in hospital organization by a rapidly retreating army such as the French army in the first months of the war. The rapid advance of the well-prepared German army and the constant retreating of the French and English did not permit of any permanent hospital organization. He says, "There was nothing to do but apply as many first aid dressings as practicable to the wounded in the immediate neighborhood of a surgical unit, and then leave them on the field to care for themselves, where those who survived necessarily became prisoners."

An exhaustive study of the nature of the wounds commonly seen was made. He did not find that bullets were mutilated or shaped in any way to obtain especially explosive effects, but these latter seemed to be the rule either at very close range or at very long range. Why this should be the case has never been satisfactorily explained, although several theories are offered to account for it. Owing to the unique nature of present-day warfare special forms of wounds predominate. Cutting and thrusting wounds, such as those inflicted by saber, bayonet, and lance, are about 5 per cent. of the total number as contrasted with the Franco-Prussian War of 1870 when they were only 6/10 of 1 per cent. Pistol wounds are extremely rare in this war. The wounds from hand grenades are very frequent on account of the nature of the trench warfare which renders rifle shooting in-

effective. These grenades, in addition to the regular forms, are improvised from empty cans and filled with any available odds and ends of metal which might damage a foe; the wounds inflicted cause great mutilation and are always infected. It is this variety of wound which has given opportunity for the surgeons at the American Ambulance Hospital to perform some really marvellous plastic surgery. One must see "before and after" pictures in Dr. Fauntleroy's book to appreciate the results. A special form of wound which certainly appears for the first time on earth with this war is caused by steel darts from above. These are let loose in bundles of a thousand at a time by aviators at great heights, are weighted to stay point downward, and acquire tremendous momentum by the time they reach the earth. The wounds inflicted by them are clean-cut, punctured ones.

The great interest this book has for the profession in this country lies, of course, in the fact that we should face similar conditions in the event of war with a European country and must be ready to cope with the peculiarities of trench warfare, explosive wounds, poisonous gases, and attacks from above.

BLOOD PRESSURE IN TYPHOID FEVER.

BLOOD pressure falls below normal in typhoid fever, remains low until convalescence is established, when it slowly returns to normal. Investigations by numerous observers seem to demonstrate that typhoid fever lowers the blood pressure more than any other acute disease. Moreover, there does not appear to be any direct relation between the gravity of the attack and the fall of blood pressure, very low readings being found in quite mild cases. When, however, typhoid perforation occurs, hypertension, according to Crile, is the rule and is of value in the diagnosis of the condition. H. D. Rolleston in the *Medical Press*, March 15, 1915, gives the results of investigations made by him with respect to blood pressure in typhoid fever. He says that while of interest, it cannot be said to afford much guidance in diagnosis, prognosis, or treatment. He summarizes as follows: (1) In a series of cases of typhoid fever the blood pressure was found to be subnormal in 93.8 per cent., the extent and duration of the depression being, as a rule, in direct relation to the severity of the attack. (2) The blood pressure of the female patients showed a decided tendency to keep at a lower level than that of the males. (3) A considerable percentage (48.8) of the patients who were discharged at periods ranging from the fifth to the twenty-third weeks of disease never regained the normal blood pressure for their age during their stay in hospital. (4) In the great majority of cases the blood pressure fell below 100 mm. at some period of the disease. (5) In the majority of cases the blood pressure was higher in convalescence than in the acute stage. (6) In 93.1 per cent. of the convalescent cases the readings in the recumbent and erect positions were the same, or the recumbent was higher than the vertical record until convalescence was firmly established, this "hypotension of effort" in some cases persisting until the patient's discharge. (7) The only complications which affected the blood pressure were intestinal hemorrhage and myocarditis, which

caused a considerable fall, and cholecystitis and pleurisy, which were accompanied by a transient rise. (8) Though not essential to the successful management of a case, sphygmomanometry furnished interesting illustrations of the profound effect produced on the cardiovascular system by the toxin of typhoid fever.

THE POLYCHROMATOUS PHYSICIAN.

WE all know, of course, from dabbings in psychology that colors have an effect on our moods, a saffron tie makes us languorous, while a purple one inspires us to noble deeds. Green produces a state of tranquillity, while blue depresses us. And so on. But now the chromatic scheme of things entire has invaded the operating room, that hitherto domain of the strictly practical. Last September Dr. Berkeley Moynihan wrote to the *Lancet* stating that for two and a half years he had been using green sheets and towels instead of white ones in the operating room, as they were more restful to the eye; he had also painted his walls green and covered the floor with green material. This suggestion was copied by some American journals. In the next number of the *Lancet* Dr. Milligan expresses himself as being in favor of such a scheme, but Dr. Whiteford is much more enthusiastic. His operating room he has done tastefully in light French blue, the surgeons are dressed in white, the nurses blue, and the onlookers red. In the next issue a Dr. Jeans states that he is doing his operating rooms in blue this year. And so the chromatic surgeons contribute their impressionistic ideas of operating rooms. In time let us hope we will have the perfect polychromatous physician; he will bewilder us with some such display as this: The anesthetic room will be in rainbow colors, signifying hope; the operating room will be in red, meaning danger, the new assistant will be green, the patient's relatives will look blue, and the future will appear black. Seriously, however, it is time that some such restful shade to the eyes as light green should supplant the glaring white of many hospitals, the dazzling operating room, the cheerless corridors, and the monotonous patients' rooms.

THE MECHANICAL FACTOR IN THE GENESIS OF SCIATICA.

LET us suppose the case of a man unused to the sitting posture and without much adipose tissue who is compelled to sit for hours daily upon a hard bench. Does any one doubt that such behavior would manifest itself in some manner on the sciatic nerve? The phenomenon of the "leg going to sleep" is a very familiar effect of such nerve compression, but this is transitory and occurs in most subjects without real predisposition; it merely shows that the sciatic nerve is quite readily compressed. Turning now to the ordinary notions of the nature of sciatica—that it is a neuritis or neuralgia or is associated with muscular rheumatism—it is readily seen that such conceptions of the disease are far from satisfactory. Sciatica is almost always unilateral. Were it a mere metastasis or local expression of a general blood state, there would seem to be no warrant for a one-sided incidence. If, however, there is a predominant mechanical factor, the unilateral incidence is intelligible, because one-sided compression of the nerve results from an improper sitting posture, such as is also apparent

when one leg "goes asleep." In the *Deutsche medizinische Wochenschrift* for December 23, Csiky goes to great pains to develop this theory that the phenomenon of sciatica is caused by mechanical compression of the sciatic nerve of one side by improper seating. Other factors are naturally in evidence, and of these there are not a few; but clinical sciatica, he thinks, could hardly develop in the absence of this mechanical component.

News of the Week.

Death Rate in New York.—The death rate in New York City for the week ending April 1 continued low, being 15.40 per 1,000 of population, as compared with 17.47 for the corresponding week of 1915. The total number of deaths during the week was 1,649, while for the corresponding week of last year 1,831 deaths were recorded. The decrease in the mortality was marked in the infectious diseases, as well as in cancer, heart disease, influenza, lobar pneumonia, bronchopneumonia, and pulmonary tuberculosis. For the first fourteen weeks of 1916 the death rate was 15.65, as compared with 15.29 for the same period of last year.

Chicago Death Rate.—For the week ending April 1, the death rate in Chicago was 15.4 per 1,000, or exactly the same as in New York, the actual number of deaths being 736. For the corresponding week of last year the rate in Chicago was 16.5, and the total number of deaths 772. The decrease extended through all the principal causes of death, with the exception of diarrhea and enteritis among children under two years of age, in which group there was a considerable increase.

Protest Sale of Stray Dogs.—The action of the Board of Commissioners of Ridgefield Park, N. J., in arranging to sell to a medical institution in New York all stray dogs picked up in the village has aroused a storm of protest. The sentimentalists refer to the "ghastly tortures of vivisection" and "the unspeakable horror" of the experiments, while the utilitarians point to the fact that the village will receive one dollar for each dog and will in addition be spared the expense of asphyxiating and burying the animals, besides, perhaps as an afterthought, aiding in the war of scientific treatment.

Navy Medical Corps.—An examination for admission into the Medical Corps of the Navy will be held on or about June 15, 1916, in various navy yards throughout the country. Applicants must be between 21 and 30 years of age, graduates of a reputable school of medicine, and citizens of the United States. Full details of the examination and of the requirements can be obtained by applying to the Surgeon General of the Navy, Navy Department, Washington. Successful candidates are appointed assistant surgeons in the Medical Reserve Corps, and if so recommended are subsequently assigned to duty, with full pay and allowances, in attendance upon a course of instruction at the Naval Medical School, Washington. Upon completion of this course, the student officers are given their final examination, and, if found qualified, are commissioned as assistant surgeons in the regular Medical Corps of the Navy. The pay of an assistant surgeon is \$2,000 per year on shore duty and \$2,200 at sea, with quarters or their equivalent. After three years' service assistant surgeons are eligible for examination for promotion to the grade of passed assistant surgeon. Promotions to still higher grades

are made in the order of seniority to fill vacancies as they occur.

Public Health Service.—Candidates for admission to the grade of assistant surgeon in the United States Public Health Service will be examined on May 31, 1916, at the Bureau of Public Health Service in Washington and at a number of the marine hospitals of the service. Candidates must be between 23 and 32 years of age, and graduates of a reputable medical college, and have had at least one year's hospital experience or two years' professional work. The examinations are: 1, physical; 2, oral; 3, written; 4, clinical, and usually cover a period of ten days. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order; they will receive early appointments. Assistant surgeons receive \$2,000 a year, and after four years' service are entitled to examination for promotion to the grade of passed assistant surgeon, at a salary of \$3,000. Full details and invitation to appear before the board of examiners can be obtained upon application to the Surgeon General, Public Health Service, Washington, D. C.

Honor Dr. Comfort.—The trustees of the New York Medical College and Hospital for Women gave a luncheon at Delmonico's on April 8 in honor of the fiftieth anniversary of the graduation of Dr. Anna Manning Comfort, the only surviving member of the first class graduated from the college. Dr. Comfort and Mr. Jefferson Levy, one of the incorporators of the institution, were the guests of honor. At the commencement exercises of this first class addresses were made by Henry Ward Beecher, Peter Cooper, Horace Greeley, Lucretia Mott, Elizabeth Cady Stanton, and Dr. Lozier, dean of the college. The endowment of a scholarship at the college, to be known as the Anna Manning Comfort scholarship, was announced at the luncheon.

Dental Hygienists.—Because of the great need for increased attention to the condition of the teeth of school children in New York, of whom, it is asserted, at least ninety per cent. require dental treatment, the committee on child hygiene of the advisory council of the Health Department recently appointed a sub-committee to study and report on the desirability of using dental hygienists in the schools. The sub-committee has recommended that a trial of the surface cleaning of children's teeth be made as soon as possible in one or more centers, preferably public schools, and that at the same time the children be given instruction in oral hygiene. In order that the work may be legally safeguarded, there has been passed by the Legislature and signed by the Governor a bill which provides that any dental dispensary or infirmary legally incorporated and maintaining a proper standard and equipment may establish for women students a course of study in oral hygiene. Such students shall present evidence of one year's attendance at high school, and after one year may be graduated as dental hygienists, upon complying with the preliminary requirements to examination. After satisfactorily passing the examination these students shall be registered and licensed as dental hygienists by the Regents, under such rules as the Regents may prescribe. Any licensed dentist, public institution, or school authorities may employ such dental hygienists, who may remove lime deposits, accretions, and stains from the exposed surfaces of the teeth, but shall not perform any other operation on the teeth or tissues of the mouth. The

law follows the enactment of similar ones in Massachusetts and Connecticut, and it is expected that with the preventive steps made possible by the employment of such workers the condition of the teeth of the coming generation may be greatly improved.

Free Radium Clinic.—Through the generosity of Col. George Fabyan of Geneva, Ill., the Colonial Hospital, Geneva, has been given the use of 100 milligrams of radium for the treatment of cases of cancer and diseases of the skin. This is said to be the largest amount owned by any individual in Illinois.

New Typhus Serum.—Newspaper dispatches from Paris state that Dr. Pierre Roux, director of the Pasteur Institute, on April 4, announced to the Academy of Sciences the discovery of a serum for the treatment and prevention of typhus fever. The discovery is said to be the result of the work of Dr. Nicole, director of the Pasteur Institute in Tunis.

Defends Pay Clinic.—Dr. S. S. Goldwater, superintendent of Mt. Sinai Hospital, has replied to the adverse criticisms from some medical societies and some individual members of the medical profession on the plan of establishing at the hospital a night pay clinic. Dr. Goldwater said that the plan was not yet complete and, therefore, could not be considered thoroughly from a professional standpoint. "Experience has shown," continued Dr. Goldwater, "that persons of moderate means who are in need of the services of high-grade specialists have the greatest difficulty in obtaining them, for such physicians, either in their private offices or in the field, do not give their services for nominal fees. This problem, it is universally conceded, must be solved, and a great many patients are forced to solve that problem in their own way by going to free dispensaries. In fact, many such patients are referred to the dispensaries by general practitioners, who send cases to the dispensaries for diagnosis. This is especially the case when the making of diagnoses requires the use of special apparatus and equipment and the cooperation of a number of physicians. There is a large number of patients who certainly could not be put in the pauper class who cannot afford to go to the specialists. The question before us is how to solve the problem, and to this the trustees have been devoting much attention. There is no reason why there should be anything hostile to the profession in this plan, for we seek the cooperation of the medical profession in developing it. There have for several years been evidences of the need of such a plan."

Death of Mrs. Juilliard.—Mrs. Helen Cossitt Juilliard of New York, who had for years been a generous benefactor to medical charities, died at her home last week after a long illness. More than twenty years ago Mrs. Juilliard gave to St. John's Guild its first floating hospital and only last February a new hospital ship, the joint gift of herself and her husband, was launched at Wilmington, Del. Mrs. Juilliard had been also for many years a manager of the Lincoln Hospital and Home, and with her sister, the late Mrs. Dodge, had given to the New York Orthopedic Dispensary and Hospital funds for the erection of a portion of the new building in East Fifty-ninth Street. Of her time and interest she had also given freely and her death will be deeply felt.

Appeal for Blinded Soldiers.—Constructive relief work among the blinded British, French, and Belgian soldiers is to be coordinated and enlarged

by the B. F. B. Permanent Blind Relief War Fund for Soldiers and Sailors, recently organized in New York, and a nation-wide appeal for the support of the movement was issued last week. It is said that six months' training is sufficient to educate the thousands of now useless blind men in trades in which they can support themselves and at least partially support their families.

Personals.—Dr. AMOS O. SQUIRE of Ossining was appointed acting physician and surgeon at Sing Sing prison on April 6, succeeding Dr. C. W. Farr, resigned. Dr. Squire has treated a number of inmates of the prison with radium furnished for the purpose by Mr. Frank A. Vanderlip, and has also served for two terms as coroner of Westchester County. It is said that the appointment will soon be made a permanent one.

Dr. NELLIS B. FOSTER, assistant professor of medicine at Cornell University Medical School, has accepted the appointment of professor of medicine at the University of Michigan, Ann Arbor.

Dr. MALCOLM SEYMOUR of Boston has been appointed State medical director to fill the place made vacant by the resignation of Dr. Horace D. Arnold. Dr. Seymour was graduated from the Harvard Medical School in 1904, and for several years past has served as medical examiner for Saving Bank Life Insurance in Boston and vicinity.

Dr. J. B. FREUND of Butte, Mont., has been appointed physician of Silverbow County, filling the vacancy caused by the death of Dr. Joseph A. Tremblay.

Gift to Medical School.—By the will of the late Col. E. A. Knox of this city, the New York Medical College and Hospital for Women receives a bequest of \$5,000.

Spring Medical Meetings.—The annual meeting of the Medical Society of New Jersey will be held at Asbury Park on June 20 to 22, instead of at Spring Lake, as previously announced. It is believed that the large number of delegates expected can be cared for more comfortably at Asbury Park than at the smaller place.

The Medical Association of the State of Alabama will hold its annual meeting at Mobile from April 18 to 22, inclusive. On the second day a large public meeting will be held.

The eighteenth annual meeting of the American Proctologic Society will be held at the Hotel Statler, Detroit, on June 12 and 13, 1916, under the presidency of Dr. T. Chittenden Hill of Boston. The secretary is Dr. Alfred J. Zobel, 518 Stevens Building, San Francisco. The preliminary program contains a list of twenty-four titles, promising a full and interesting meeting.

New Medical Society.—The Chicago Society of Medical Research was organized recently with forty-one physicians as charter members. The society has for its purpose the study and investigation of disease and the advancement of the science of medicine. The following officers have been elected: *President*, Dr. Charles J. Lewis; *First Vice-President*, Dr. M. E. Simmons; *Second Vice-President*, Dr. E. J. Danek; *Secretary-Treasurer*, Dr. Edwin S. Antisdale.

Williamsburg County (S. C.) Medical Society.—The annual meeting of this society was held at Hemingway on March 23, when officers for the ensuing year were elected as follows: *President*, Dr. A. G. Eaddy, Johnsonville; *Vice-President*, Dr. T. S. Hemingway, Kingstree; *Secretary-Treasurer*, Dr. Elbert A. Simmons, Hemingway.

Obituary Notes.—Dr. WALTER C. HANSCOM of Minneapolis, Minn., a graduate of Rush Medical College, Chicago, in 1884, and a member of the Minnesota State Medical Association and the Hennepin County Medical Society, died at his home, after a long illness, on March 23, aged 61 years.

Dr. JOHN SPECHT of Superior, Wis., a graduate of the College of Physicians and Surgeons, Keokuk, Ia., in 1883, and a member of the State Medical Society of Wisconsin and the Douglas County Medical Society, of which he was president, died in the Eitel Hospital, Minneapolis, from appendicitis, on March 8, aged 56 years.

Dr. AXEL F. SWANSON of Southampton, Mass., a graduate of the Albany Medical College in 1913, and a member of the Medical Society of the State of New York, the Albany County Medical Society, and the Massachusetts Medical Society, died at his home on March 19, aged 25 years.

Dr. FREDERICK H. BANGS of San Jose, Cal., a graduate of the Cleveland University of Medicine and Surgery, Cleveland, Ohio, in 1880, and a member of the American Medical Association, the Medical Society of the State of California, and the Santa Clara County Medical Society, died at his home on March 13, aged 58 years.

Dr. LEWIS C. SHUTT of Oliver, Ind., a graduate of the Eclectic Medical College, Cincinnati, in 1889, died from Bright's disease and pneumonia at the Deaconess Hospital, St. Louis, on March 17, aged 60 years.

Dr. REUEL STEWART of Philadelphia, Pa., a graduate of the University of Pennsylvania, Department of Medicine, Philadelphia, in 1870, and a member of the Obstetrical Society of Philadelphia, died at his home on March 28, aged 86 years.

Dr. JOSEPH JONES of Stockbridge, Mass., a graduate of the Eclectic Medical College of Pennsylvania, Philadelphia, in 1896, died at his home from Bright's disease on March 20, aged 76 years.

Dr. W. E. HEADEN of Morehead City, N. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1891, and a member of the American Medical Association, the Medical Society of the State of North Carolina, and the Cartaret County Medical Society, died at his home on March 19, aged 49 years.

Dr. W. W. BARNES of Louisville, Ky., died at his home on March 18, aged 64 years.

Dr. IRVING S. BALCOM of New York, a graduate of New York University Medical College in 1887, and a member of the Bronx Medical Society, died at his home, from heart disease, on March 30, aged 53 years.

Dr. HENRY BERLIN of Chattanooga, Tenn., a graduate of the University of Tennessee, Medical Department, Memphis, in 1885, and a member of the American Medical Association, the Tennessee State Medical Association, and the Hamilton County Medical Society, died at his home, after a long illness, on April 1, aged 65 years.

Dr. JOHN GORDON RENNIE of Petersburg, Va., a graduate of the University College of Medicine, Richmond, Va., in 1899, and a member of the American Medical Association, the Medical Society of Virginia, and the Petersburg Medical Faculty, died in a New York hospital on March 30, aged 42 years.

Dr. THOMAS HUGH O'CONNOR of Boston, Mass., a graduate of the College of Physicians and Surgeons, Baltimore, in 1893, and a member of the American Medical Association, the Massachusetts Medical Society, and the District Medical Society,

died at his home on March 30, from injuries received in a fall on March 20, aged 50 years.

Dr. GEORGE A. FAGAN of North Adams, Mass., a graduate of McGill University Medical Faculty, Montreal, in 1898, died in the Samaritan Hospital, Troy, N. Y., on April 1, aged 45 years.

Dr. KENNETH GUNSOLUS of Detroit, Mich., a graduate of Queen's University Medical Faculty, Kingston, Ontario, in 1871, and a member of the Michigan State Medical Society and the Wayne County Medical Society, died, after a brief illness, on March 24.

Dr. JOHN B. FINDLEY of Des Moines, Iowa, died suddenly at his home, on March 26, aged 67 years.

Dr. W. P. MCGOVERN of Cedarburg, Wis., a graduate of the Rush Medical College, Chicago, in 1882, died at his home after a long illness, on March 23, aged 58 years.

Dr. THEODORE B. SACHS, a graduate of the University of Illinois, College of Medicine, Chicago, in 1895, and a member of the American Medical Association, the Illinois State Medical Society, and the Cook County Medical Society, and formerly head of the Chicago municipal sanatorium for tuberculosis, died suddenly at the Edward Sanatorium, Naperville, Ill., on April 2, aged 48 years.

Dr. CHARLES A. JESSUP of St. Louis, Mo., a graduate of the Missouri Medical College, St. Louis, in 1877, died at his home on March 26, aged 65 years.

Dr. ELIHU L. COOK of Harlan, Iowa, a graduate of the College of Physicians and Surgeons, Keokuk, in 1876, died suddenly at his home, on March 28, aged 77 years.

Dr. OTHO MAGRUDER MUNCASTER of Washington, D. C., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1866, and a member of the Medical Society of the District of Columbia, died at his home, after a short illness, on April 1, aged 72 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

DISTRICT NURSING—REPORT OF THE CENTRAL COUNCIL—RULES FOR NURSES—EFFECT OF THE WAR ON NURSING.

LONDON, March 7, 1916.

THE Central Council for District Nursing in London has adopted the first annual report of its executive committee endorsing the work in relation to measles, German measles, and whooping-cough, which it was hoped would have great influence in diminishing the mortality from these diseases. It is undeniable that the greater the care bestowed on cases from their commencement the less will be their mortality and the fewer their complications. But it is a common observation that the public regards these diseases as slight ailments which the majority of children must pass through, and hardly ever serious. They are, therefore, quite commonly left to the care of the nurse, who too often neglects to ask for medical advice until too late.

Notification should be of great value in restricting the diffusion of the infection and, therefore, public authorities may well give further attention to the means of carrying it out. In some districts the authorities have entered into contracts with the local associations for nursing, and the arrangements seem to have answered

fairly well, especially where care has been taken to ensure efficient training and special instruction of the nurses under regulations which prevent them from assuming to interfere with directions which they should be required most strictly to obey.

For the central council Dr. F. F. Caiger has drawn up indications for the guidance of a nurse in reporting cases of measles to the medical officer of health, any attack of which in a child under five years old should be regarded as serious. In older persons the patient's condition is denoted by the severity of the attack or by the development of complications, the most frequent of which is bronchitis or bronchopneumonia. The severity may be gauged by the temperature and pulse-rate. Complications will be noted by rising respiration, reaching sometimes 50 to 60 per minute, with frequent cough, fretfulness, dusky lips, and a temperature of 101° to 103° or more. Occasionally in a severe case the temperature does not rise, though rapid breathing, 60 or more, listlessness, and prostration indicate the dangerous state of the patient. Otitis, ophthalmia, and diarrhea are other complications.

The council requires the district nurses to observe strictly the rules it has laid down when nursing measles or whooping-cough, as in both the infection is by the breath and secretions of nose and mouth. They are to be specially careful as to the disposal of anything contaminated by them. A separate apron is to be worn when attending each infectious case, to be kept at the patient's home, put on when entering the room, the sleeves being previously turned up; when possible every cup, spoon, fork, etc., used by the patient is to be kept for his separate use; when impossible, the article should be boiled after each time of using it. All rags, lint, cotton, wool used for discharges must be burned at once or placed in a dressing-tray or on paper until it can be. Damp swabs are better than dry, and should be wrung out of a liquid disinfectant. The nurse must avoid as far as possible bringing into close proximity to the patient any article of equipment which is not actually required at the time. These and other obvious details if conscientiously observed will enable the nurse in most instances to reduce to the minimum the risk of conveying the infection to other patients.

The effect of the war on the nursing associations has been that many of their staffs have left for the front, the vacancies having been filled up to a considerable extent by the engagement of temporary substitutes. But the work has been heavier on those who have remained. It has further increased because some of the metropolitan infirmaries have been closed. The report admits that the doctors have been so pressed that a great deal more work than usual has been left to the nurses. Some attempt to explain this is made, but the council would do better to take measures for preventing it. It is true that many doctors and nurses, too, have gone to the front, but there are many remaining at home who could supply their places. In some districts a decrease of work is reported and attributed partially to the prosperity of the people from abundance of occupation. The council is to be congratulated on its remarkable financial position; it has been able to restrict expenditure to the bare cost of printing and stationery.

Progress of Medical Science.

7. Recent Progress in Psychiatry. Henry R. Stedman.

1. Cesarean Section: Indications, Technique, and Time of Operating.—Charles M. Green draws his inferences and conclusions on this subject not only from the results of a previous series published in 1907 but from the work of the past eight years, covering above three hundred cesarean sections. In regard to the time of operating, except in rare cases such as cardiac, toxemic, and placenta previa conditions, it is generally best not to operate until the parturient has been in labor for a certain number of hours, and he states the advantages of such procedure as follows: (1) It is certain that the pregnancy has reached full term. Abdominal cesarean section is done largely in the interest of the baby in elective operations, and it is a pity to deprive the baby of the last two or three weeks of intrauterine development. (2) There is greater certainty that in the convalescence the uterus will have free drainage. Labor continues naturally until the cervix is taken up and the os uteri expanded an inch or two allows for free drainage, and risks of lochial retention are avoided. (3) There is less bleeding from the placental site. (4) The uterine scar is stronger. Sutures applied to a wall thickened by several hours of uterine activity allow for a scar as strong as, if not stronger than, the remainder of the uterus. (5) It is more certain that abdominal delivery is really necessary in the interest of mother and baby, or both, in the so-called borderline cases. Humility is good for mortals, and it may be as well acknowledged that no man can say with certainty what any given woman may do in labor. Green outlines twenty cases and says that out of this number only one mother died—from embolism—and that there was no fetal loss. From his present knowledge and experience he draws definite conclusions, part of which are given here: (1) Every pregnant woman should receive the best of antepartum study and care in order that the obstetrician may understand the conditions presented. (2) Except under special conditions, labor should be allowed to progress for a number of hours. (3) During the observation of labor vaginal examinations should be avoided, and progress noted by external and rectal palpation. (4) Except when easy access to the pelvis is necessary, the supraumbilical incision is preferable. (5) There is no reason for eventration of the undelivered uterus. (6) Time should be taken for a triple-layer suture of the abdominal wall, especial care being used with the fascia, which is best closed with overlapping and mattress stitch. (7) The uterine wall, thickened by some hours of muscular contraction, should be closed carefully with deep and seroserus absorbable sutures. (8) The uterus was created a movable organ; it should be allowed to remain so, at least in all married women, until after the climacteric.

3. Cesarean Section—Overdone.—Foster S. Kellogg states that this operation is the most overdone one in Boston at present, under the idea or delusion that it is an absolutely safe procedure, and the reason it is considered safe is because it is simple. That does not follow. He quotes Dr. Lee in showing the general per-

centage of mortality, and states that in regard to the statistics gathered around Boston and elsewhere, figures and conditions can be juggled to mean almost anything desired. He asks on what indications is it being advised in this community, and gives the honest answer as "almost anything that keeps a baby from flopping into the world itself." He states the clearly indicated reasons for doing cesarean section, and then gives the following ones in which it is advised usually unwisely: (1) Primary cesarean section for women with unfit nervous systems and general makeup. (2) Cesarean section for primiparous breech, where the presentation is not due to a manifestly small baby in relation to the pelvis. (3) Cesarean section on the pelvic indication. (4) After attempted high forceps in which the head could not be made to enter the superior strait; cesarean section has been done for prolapsed cord in a young primipara, three-fourths dilated, transverse, with true conjugate $3\frac{1}{4}$ in. and fair sized baby. (5) Cesarean section in toxemia of pregnancy, without convulsions, and with eclampsia. (6) Cesarean section for breaking or broken cardiacs. (7) Cesarean section performed any time in labor and under all conditions. (8) Cesarean section by general surgeons untrained in obstetrics. (9) Cesarean section has been done in some instances for personal advertisement or for commercial reasons on account of the poor fee for poor work that is often paid for ordinary deliveries. These cases are rare, but do exist. Kellogg states in conclusion that the old attitude of many general men toward cesarean section persists—they still believe it is the saving operation of last resort. It is usually stated that the mortality of cesarean babies is zero. Men with good cesarean experience consider that their patients are all well afterward, but Kellogg regards this as an extremely optimistic view, as a large number of women are very well aware in consequence of scar pain, adhesions, bowel irregularity, or nervous knowledge. The author says that his object in presenting the subject under this aspect is to show that here, as elsewhere, a good thing exploited is apt to go bad.

6. A Second Statement Regarding the Respiratory Mechanism in Pneumonia.—Newburgh, Means, and Porter in a former communication presented evidence that in cats with pneumonia the reaction of the respiratory mechanism to carbon dioxide is greatly impaired. This reaction is also impaired in dogs with the same disease. They cite examples of some of their experiments and state that in atmospheric air these pneumonia dogs and these normal dogs breathed the same number of cubic centimeters per minute. Additional evidence is as follows: (1) As the disease advances the carbon dioxide reaction diminishes; so may the initial ventilation. (2) If the failure to react were due to the loss of respiratory space from hepatization of the lung, large consolidations should be accompanied by a large reduction in the carbon dioxide reaction, and small consolidations by small reductions. Such is not the case; there is no parallel between the area of consolidation and the amount of the reaction. (3) The impairment of the respiratory mechanism increases progressively, while the area of consolidation may remain unchanged. By experiments they have been able to show that the failure of the respiratory mechanism in pneumonia may be prevented by section of the vagus nerves. The authors of this paper have worked out the following conclusions: (1) The reaction of the respiratory mechanism to carbon dioxide is greatly diminished in pneumonia. (2) The graver the disease the less is the reaction. (3) The section of the vagus nerves may prevent this depression of the respiratory mechanism.

1. Our Duty to Mental Defectives of the Present Generation.—Sajous states that eugenics aims, as we know, to improve mankind through heredity, but that it will require a long time for the mass of people to be influenced to any material degree. Laws fail because they will not be enforced, and then will be shelved. He quotes M. W. Barr of Elwyn, that there are 350,000 avowed mental defectives in the United States, and that 328,000 of these are at large "perpetuating unrestrained the defilement of the race." Basing its estimate on a study of the schools of thirty-one American cities, the Russell Sage Foundation has shown that over one-fifth of all the children in the public schools of the United States belong to the retarded class—to say nothing of those who do not attend school. How could this evil be stemmed? How could we, physicians, protect the child of today, and the unborn but doomed of tomorrow, for whose welfare we are, more than any one else in the world, responsible? Sajous says that we have means for the salvation of a large proportion of the infants of our day from feeble-mindedness, and precocious insanity in older children, through an adequate conception of the meaning of the ductless glands in the morbid process. In the functional disorders of these organs we have the underlying cause of several of the most common mental diseases. Also that any disease capable of injuring the ductless glands sufficiently to inhibit their functional activity impairs correspondingly the development and functional activity of the brain by reducing the supply of secretions this organ requires to carry on these physiological processes. The main underlying cause of defective mentality in both parent and offspring is inherited deficient activity of the ductless glands. Summarizing his foregoing statements, Sajous concludes: (1) The ductless glands, owing to their controlling influence over nutrition and development of the body, including the brain, supply the means to this end in respect to the mental defectives represented by the various grades of idiocy and dementia præcox. (2) The mental and physical state of all pregnant women as regards the functional efficiency of their ductless glands should invariably be established. If deficient, organotherapy should be used to protect them against renal disorders and convulsions through toxemia, also their offspring against imperfect development and mental deficiency. (3) The development of all infants should be watched by the family physician, especially if the family history be tainted, and if symptoms arise in the child, organotherapy should be instituted. Twenty thousand cases of dementia præcox are admitted to the insane asylums each year. By organotherapy this could be arrested.

5. Forestry and the Public Health.—Henry Reed Hopkins says that to Americans no subject is of more vital importance than that of forestry. Without our forests the fertility of our soil, the profits of our farms and gardens, the building, the operating, the profits of our railroads, mines of coal and iron, and the maintenance of our homes, in fact, our civilization disappears, and what the traveler sees abroad in many countries will be seen on the plains of America. During the last twenty years the problems of forestry have been en-

thusiastically studied in our country. The forests are the kings, the royal family of that kingdom which includes all varieties of beautiful plants and flowers, fruits and grains. We should not overlook the important biological fact of man's intimate dependence upon the food, oxygen, and that man is constantly producing large quantities of carbonic acid, which is poisonous and in a certain proportion in the air makes the same unfit to breathe; and we may recall that our forests exhale vast quantities of oxygen and generously absorb like quantities of carbonic acid. The rivers of America break into devastating floods of increasing frequency and severity, producing an annual waste of over \$237,000,000, and which will increase until care of our forests and reforestation again provides our hills and mountains and watersheds with that protection which was theirs by Nature's provision and which alone prevents floods. Denudation or the washing away of the soil itself produces enormous losses. Added to this the relation of forests to every side of civilized life must be considered, especially to the existence of human life, the perfection of mankind, the prevention of disease; this is the more important side to the physician. This dogmatic statement is based upon a consideration of the rôle played by forests in the production of climate—air, light, humidity, and temperature, the environment of man, the factor of supreme importance in man's existence and welfare.

1. The Etiology and Treatment of Rat-Bite Fever.—Wilder Tileston states that rat-bite fever is an infectious disease following the bite of a rat, or more rarely the bite of some animal having contact with rats (weasel, ferret, cat). There is an incubation period averaging about two weeks, which is followed by one or more febrile attacks, accompanied by a characteristic rash. These paroxysms tend to recur with remarkable regularity at intervals of from five to ten days, and the duration of the attack averages from two to three days. The temperature rises gradually, to attain the maximum on the second day, and falls by crisis with profuse sweating. Severe muscular pains and dysphagia are often prominent symptoms. In the interval between the attacks the patient feels almost well. The mortality of the reported cases, of which there are about eighty, is ten per cent. The prophylaxis is simple. Immediate cauterization of the wound either by strong carboic acid, or the actual cautery, has proved a sure preventive. Hata has reported eight cases treated with salvarsan, in which the results were striking, five out of the eight patients being cured by a single injection.

Tileston's cases bring the total of those treated up to twelve, with cure in ten, or eighty-three per cent. The dosage is the same as for syphilis. He summarizes the results of his work as follows: (1) In a typical case of rat-bite fever, organisms were found in the blood, closely resembling the *Streptothrix muris rattii* of Schotmüller and Blake. They were present in each febrile paroxysm and absent in the intervals. They were readily demonstrated by dark-field illumination, but with difficulty by staining methods, probably on account of a strong tendency to fragmentation. Blood cultures and inoculations of animals with the blood were negative. (2) The administration of salvarsan was followed by immediate cessation of the paroxysms. (3) An abortive case of rat-bite fever is reported.

2. The Cause of Gastric Ulcer.—W. E. Burge and E. L. Burge report the results of their experiments done at the physiological laboratory of the University of Illinois, and state that a great many theories have been advanced concerning the cause of gastric ulcer, the main feature of which is that there is a decreased resistance of limited areas of the gastric wall followed by the digestion of these areas by the unrestricted action of the pepsin. Their investigation is concerned with the cause of this diminished resistance. In view of the fact that pepsin is easily destroyed by oxidation, that the cells of the mucosa possess oxidative properties, and that these cells become easily digested when these properties are decreased, the hypothesis is advanced that the mucosa is not digested under normal conditions because the pepsin immediately in contact with the wall of the stomach is rendered inert by the oxidative processes of the cells. This theory assumes that normally a balance exists between the oxidative processes of the cells of the mucosa and the digestive action of the pepsin in the stomach, and if this balance be destroyed, thereby decreasing the oxidative processes of the area, this area should be digested by the pepsin with the production of ulcer. They carried out their experiments on dogs and formulated the following conclusions: The decreased resistance of a circumscribed area of the stomach to the digestive action of gastric juice is due to a decrease in the oxidative processes of the cells of the area. Gastric ulcer is due to the subsequent digestion of the area by pepsin. The resistance of unicellular organisms (paramycium) to the digestive action of the proteolytic enzymes can be increased or decreased by increasing or decreasing the intensity of the oxidative processes of the organisms, the greater the intensity of the oxidative processes the greater the resistance, and vice versa.

6. The Effects of Tethelin.—T. Brailsford Robertson announces that as the result of his work in the Rudolph Spreckels Physiological Laboratory of the University of California he has succeeded in isolating the growth-controlling principle from the anterior lobe of the pituitary body. He gives the method employed for isolating this substance which he calls tethelin. Tethelin probably contains an iminazolyl group, and to this extent may be regarded as being related to the physiologically active substances of the posterior lobe of the pituitary body, but it is not possessed of the same characteristic physiological activity of these substances. The average yield from 300 ox pituitaries is found to be from 2.6 to 3 gm.; each anterior lobe, therefore, may yield about 10 mg. of tethelin. The action of tethelin in doses of 4 mg. per diem administered by mouth to mice between four and sixty weeks of age consists in a marked retardation of the early (preadolescent) growth in weight, and an equally marked acceleration of postadolescent growth. Mice which have received tethelin are much more compactly and firmly built than normal animals of the same age. Weight for weight, the tethelined animals are smaller than normal, and, size for

size, they are heavier. The favorable effect on the nutrition of the skin is exceedingly marked; the coats of adult males which have been tethelin-fed, even at fourteen months of age, retain the glossy, silky appearance of the coats of young animals. Robertson also investigated in order to discover whether there was an acceleration of that species of internal growth which consists in the replacement of tissue lost through excessive tissue waste consequent on any circumstance leading to an increase in nitrogen output, as fevers, or a curtailment of nitrogen input, as inanition. Ten male and ten female mice were used for the experiments, and were deprived of food, but allowed free access to water for a period of twenty-four hours. They were weighed at the beginning of the fast, and at regular intervals thereafter, and at the end of six hours there was a break in the curve of the chart together with an acceleration of the rate of loss of weight. This probably indicates that at the end of six hours' fasting the alimentary canal is completely emptied of its contents; the subsequent loss of weight may be attributed largely if not wholly to loss of tissue substance. At the end of twenty-four hours the animals were enfeebled and the weight lost was from ten to eleven per cent. of the original weight. The animals were then divided into four groups of four or five, and one batch of males and one of females were given tethelin hypodermically; the other two batches were used as controls and received no tethelin, and they were all given simultaneously an abundant supply of food. This experiment was carried out for seventy-two hours and the animals were regularly weighed. At the end of thirty-six hours the percentage of loss regained in the male controls was 91, and in the treated 104, this being the greatest percentage of gain, and in the female controls at the end of the same time it was 104, and in the treated 117. Robertson also experimented with tissue repair in the healing of wounds and found at the end of six days the wounds in two of the control animals were still filled with granulation tissue, while in the animals which had been given tethelin the granulation tissue had been replaced by scar tissue. He summarizes as follows: Experimental results indicate that tethelin, the growth-controlling principle isolated from the anterior lobe of the pituitary body, exerts, when administered hypodermically to mice, a remarkably stimulating action on tissue repair, as expressed in the replacement of tissue lost during a preceding period of inanition or in the healing of granulating wounds.

12. A Case of Mercurial Poisoning with Recovery.—Cohen and Bernard give an account of a patient, a woman aged 28, who was admitted to the German Hospital on November 28, 1915, in a semicomatose condition and very irrational, with the diagnosis of acute mercuric chloride poisoning. Five days previous to admission she had swallowed half a tumblerful of water in which two tablets of mercuric chloride had been dissolved. There was almost complete suppression of urine at least twenty-four hours previous to admission. The following treatment suggested by Lambert and Patterson was administered on admission: (1) Colonic irrigation, gastric lavage, and hot packs twice daily; (2) continuous Murphy drips containing potassium acetate, one dram to one pint of water. The patient was given by mouth eight ounces of the following solution every hour, alternating with the same quantity of milk: Potassium bitartrate, one dram; sucrose, one dram; lactose, one-half ounce; lemon juice, one ounce; boiled water, sixteen ounces. They state that during the first five days the patient's condition seemed somewhat improved after treatment was instituted. Urine elimination varied from 200 to 700 c.c. daily. All the excre-

tions and stomach washings gave positive tests for mercury; the blood showed a marked retention of nonprotein nitrogenous and low phenolsulphonephthalein eliminations showed the absence of mercury; there was increased urine and phenolsulphonephthalein elimination. The nonprotein nitrogen and urea in the blood were markedly decreased. The remainder of her stay in the hospital until her discharge was marked by steady improvement in her general condition; the elimination of urine was about normal, and only traces of albumin with occasional hyaline casts were found in it.

February 28, 1916.

Retronasal Angina.—Blumenthal calls attention to a disease picture which while known to rhinologists is strange enough to the general practitioner. It often has an epidemic incidence and is then confounded with influenza or "one-day fever," according to its course. The condition was seen in its full expression in a ward for scarlet fever convalescents. The patients were all attacked suddenly with temperature rise to 40° C. and over, chills, prostration, and headache, both frontal and occipital. The course of the fever was decidedly septic, ending indifferently in crisis or lysis. The mouth, lungs, and urine gave negative results to examination, although the cervical region contained numerous enlarged glands, which suggested an infectious area. This was found to be the nasopharynx which was either congested throughout or the seat of a lacunar inflammation of the pharynx-tonsil. The course of the disease is somewhat as follows: A man seemingly in excellent health is attacked suddenly with fever and headache and is unable to refer his disagreeable sensations to any one locality. A few only complain of dryness and tickling in the nasopharynx, or of a somewhat stronger mucous discharge than occurs in perfect health. The voice has a nasal tone. Chest sounds are quite normal, while the pharyngeal tonsil is either intact or in rare instances reddened. Anterior rhinoscopy shows nothing anomalous, while the posterior examination may reveal a great number of changes—marked inflammation of the mucosa of the nasopharynx, especially at the vertex, with thick, tenacious, yellowish-green mucus on the upper portion of the choanæ. As a rule, all this picture subsides spontaneously in a few days, leaving no residues. Otitis media is a not infrequent complication. A renal lesion occasionally develops, and symptoms may vary from slight transitory albuminuria to a hemorrhagic nephritis, and the outcome is favorable as far as the author's experience goes. Enlarged cervical lymphnodes have never been seen to suppurate. The offending microorganism appears to be the streptococcus. In a self-limited disease of a few days' duration, not much is to be said under treatment. Menthol gives some relief. In summing up, the author draws attention to the characteristic swelling of the lymphnodes along the posterior border of the sternomastoid as far as the mastoid process.

The Edema Disease in Prison Camps.—Jürgens asks especially if this condition is connected with infectious diseases. The subject is highly involved, because these affections exhibit such startling clinical variations. We may see typhus which presents only an eruption. There is the so-called cholera-typhoid syndrome. The edema disease may be a manifestation of some of these diseases in which the admitted symptoms are latent. This affection has certain points in common with beriberi, and hence might be imputed to lack of vitamins. But its association with certain infectious diseases is unmistakable. It may complicate or follow typhus, and even precede it. It has been seen in connection with dysen-

tery, cholera, malaria, and recurrent fever. With these affections there is a profound disturbance of nutrition. The soldiers have often undergone extreme hardships. When first captured, their general condition is often wretched. After slight detention they are placed in the working camps. They bring with them the factors for infection with typhus and relapsing fever. The camps have not been ready to receive them. Conditions are ripe for epidemics among the cachectic patients. The author's studies lead to the conclusion that the edema disease has no necessary connection with infectious diseases despite the various intimate associations with the latter. It would doubtless develop to some extent if no epidemics appeared. Naturally it could figure in a vicious circle.

Münchener medizinische Wochenschrift.

February 29, 1916.

Roseola Typhosa and Paratyphosa—Eugen Fraenkel states that fifteen years ago he succeeded in showing the presence of Eberth's bacillus in the typhoid roseola and at the same time of peculiar histological changes. The skin occupied by the roseola was not merely hyperemic, but was the seat of an inflammatory process due to the metastatic deposit of the bacillus in the lymph-spaces. Foci of necrosis were even seen at times in the papillary layer. All the papillæ in a roseola are never involved, and in some of the spots only a single one. His researches at that period were limited to five cases of typhoid and the findings were quite uniform, and those in old, faded-out spots agreed fully with the picture presented by the recent lesions. The blood capillaries at no time contained any of the organisms. From a case studied on the eleventh day of the roseola, it appeared that the degree of damage inflicted on the skin is not in a direct ratio to the number of bacilli present. The true age of a roseolous lesion cannot be told from the naked eye appearances. But despite the quite individualized histological character of the lesions one could hardly make a diagnosis of typhoid in the absence of bacilli. As is well known, paratyphoid may present a roseola, and the latter has never been studied definitely from the standpoints of histology and bacteriology. The author selected a case of paratyphoid in a young child completely covered with a roseolous rash. Sections of a lesion showed the accumulation of paratyphoid-B bacillus in the lymph spaces, the blood capillaries of the papillæ being free from them. Whether differences exist between the lesions of the two diseases cannot yet be determined. It is possible that in the typhoid form there may be a greater participation of the fixed connective cells.

Endemic Goiter.—Weichardt and Wolff are continuing their work on the incidence of goiter in Bavaria, in the course of which they are keeping in touch with the reports newly published in other countries on the same subject. The experiences of Chagas of Brazil in the study of the parasitic thyreoditides of that country, together with those of Gaylord in connection with endemic goiter in fishes, lead to the same inference as the findings of the authors, to wit: that the exciting cause of goiter may be a microorganism. Incidentally it may be shown that soil is not the determining factor. In a so-called goiter spring which has for years stood in close relation to the development of the disease in men and dogs, practically no bacterial life was present, and this is true of a number of other such springs. But little calcium is found in these waters. Studies were carried out by the authors in the domain of biological reactions. Animals treated with goiter water develop an antiserum which yields reactions to the said water. This could be

interpreted of course as due to fouling of the water in transport. It is a fact of significance that in goiter localities young children, notably those of school age, are prone to suffer from the disease, but appear to acquire immunity in after years as a result. The same phenomenon is seen in malaria in malarious countries. Yet boiling goiter water does not make it goiter free, so that the disease is not strictly water-borne. In America the cause of fish goiter is associated with the slime at the bottom of the tanks in which the diseased fishes had been kept. Warm-blooded animals could be infected from this source. The authors are looking forward to a laboratory to be erected close to a goiter spring, so that water may be studied before it can become contaminated. Such water will be studied for biological reactions and with reference to physical chemistry.

Malt Soup Indications.—Graeme Mitchell says that babies under four months, premature babies, vomiting cases, or those with diarrhea and much mucus in stools do not as a rule do well on malt soup. The indications for its use are that it is a perfectly rational food and to be given in cases of weight disturbance.—*Archives of Pediatrics*.

Paralysis of Vocal Cord from Bullet Wound of Neck.—Dan McKenzie reports the case of a patient, an officer, who had received his wound in May in Gallipoli. Immediately after, he found that he could speak only in a whisper. The wound healed in three weeks and the voice returned, so that he could converse easily, although shouting soon tired it. Laryngoscopy showed the left cord to be paralyzed. The direction of the path of the bullet indicated that the left vagus was severed, without any apparent injury to the large blood-vessels and the sympathetic cord. The important question is, what is the prognosis as regards the strength of the voice after the onset of paralysis of one vocal cord? Will the condition admit of the patient using his voice in court when he again resumes his practice of law in civil life? It has been proposed that the vagus should be cut down upon and reunited.—*Proceedings of the Royal Society of Medicine*.

Conservation of Infant Life.—Edward A. Ayers lays stress upon education as the one great fundamental fact in carrying on the work of infant welfare. Beginning with wise instruction of school girls; instruction to pregnant women who come to the dispensaries, and to those after confinement; carrying instruction further to medical students, physicians, nurses, and midwives; and all assisted by general public instruction through press, lecture work, and magazines; improvement in the development of laws, both of health and labor, through the cooperation of State, city, borough, and county. The handling of this problem with absolute efficiency would quickly result in the saving of from 3,000 to 4,000 first-year infants per annum, and add from 30,000 to 60,000 citizens to our native-born population in twenty-one years.—*Journal of the Medical Society of New Jersey*.

The Effect of the War on the Medical Profession.—Charles M. Benson generously acknowledges that the war has had the effect already of leveling many prejudices, and not the least among them is that against the women physicians many of whom have been successful candidates for appointments hitherto not open to them. Dr. Louisa Garrett Anderson was the first to organize and work a Red Cross hospital, completely staffed by women physicians. Her success was so great in Paris that she was requested to organize and take charge of a hospital of 550 beds in London.—*Medical Press and Circular*.

Insurance Medicine.

Syphilis of the Nervous System in Relation to Life Assurance.—Theodore Thompson begins his argument by stating that the main result of the recent research upon syphilis of the nervous system is the demonstration of the microorganism of syphilis, not only in the acute lesion of the late secondary stage, but also in the spinal cord in locomotor ataxia and in the brain in general paralysis. The various forms of syphilis of the nervous system are the results of the differences in reaction of the body tissues to the poison of the microorganism, depending upon the number and virulence of the spirochete present, and of the power of resistance of the individual. The result is the death of the highly organized cells and fibers as the result of a circulating toxin, and another factor comes into play—the effect of strain or injury. Those fibers and nerve cells upon which most strain has been placed will be more likely to die from the toxin than those on which there is less strain placed.

Only approximate data as to the prevalence of syphilis are available. Bramwell thinks that thirteen per cent. is a fair estimate of the number of proposers for insurance who have had syphilis, and that the expectation of life in these cases may be shortened by about ten years, while Blaschko and Erb give twenty per cent. of well-to-do patients such as may become insurers. Diseases of the nervous system as the result of syphilis tend to develop early in the disease, and may be divided into cerebral syphilis, giving rise to hemiplegia and affections of the spinal cord, of which acute myelitis is most common. Fournier states that two-thirds of these cases occur in the first six years of the disease, after which there is a steady drop in the number of cases occurring. In general paralysis, however, there is a condition which is of the utmost importance in reference to insurance. This condition reaches its maximum between the sixth and twelfth year after infection. The risk is a very definite and expensive one for life insurance companies as the proposers are usually dead in the fourth decade of life. Tabes dorsalis is of less importance because it becomes chronic, and the patients may live for many years, finally dying from an intercurrent complication.

In consideration of the treatment of syphilis, Thompson says that there seems to be no doubt that a thorough treatment with mercury has a marked effect in preventing the onset of nervous complications, but there is also no doubt that syphilitic nervous disease can develop in cases that have been treated very thoroughly for a long period with mercury. A two years' mercuric treatment by no means insures the non-development of syphilis of the nervous system. It has been stated that eighty per cent. of syphilitics who develop general paralysis have been insufficiently treated. The treatment with salvarsan has not been of sufficient period of time to judge of results. Thompson has seen at least five cases of development of nervous syphilis that have received the salvarsan treatment. While the Wassermann reaction may play an important rôle with regard to syphilis, from the insurance point of view the fact that a proposer who has had syphilis has a negative Wassermann is of very little value, nor need the fact that he has a positive Wassermann reaction make him absolutely uninsurable, since treatment influences the result of the Was-

sermann reaction. It is certainly safer not to insure a patient who has had syphilis until at least five years after the date of infection, and the age at which the proposer contracts this disease is most important, as those who contract it after the age of forty develop a much more serious manifestation of the condition, and if acquired in the usual way it would seem to show that the proposer is governed by irregular habits in the latter part of life, therefore less suitable for insurance. Various observers have endeavored to estimate the mortality from syphilis, not only of the nervous system, and in all cases syphilitic lives prove to be bad ones on an average, and a very serious risk to the life insurance companies. Most insurance companies now ask the definite question as to the state of the pupil reflexes and knee-jerks. Recognition of nervous syphilis in the acute stage in the early years after infection is difficult and may be overlooked in the physical examination. The presence of nocturnal headaches and hyperesthesia in root areas should disqualify the proposer.

Thompson gives the following conclusions as to the treatment of the lives giving a history of syphilis: (1) No syphilitic proposer should be accepted unless he can bring forward satisfactory evidence of having undergone treatment for at least two years. (2) No syphilitic proposer should be accepted until there has been an interval of five years from the date of infection, and no secondary or tertiary symptoms have developed in this period. This conclusion is rather more stringent than that ordinarily accepted which ordains a three years' interval with a year's freedom from symptoms, but the very large mortality in early years, as shown by the American offices, leads to the increase of the interval after infection before which a proposal can be entertained. (3) No proposer acquiring syphilis after forty years of age should be accepted. (4) The only syphilitic cases who should be accepted are those who are perfectly satisfactory in their present physical condition, family history, and habits, and even in these cases an addition should certainly be made; for example, five years extra in a proposer of thirty-five years of age.—*The Assurance Medical Society.*

Suicide in Prussia, According to Frequency, Age, and Sex During the Year 1913.—The total number of suicides in Prussia during 1913 was 9,214 (of which number 6,831 were males). The figure for the preceding year was 8,723, an increase of 491. The average number during the periods 1909-1913, inclusive, was 21-22 per 100,000 living (the proportion of male to female amounting to 3 to 1). Individual States show wide departures from the grand average for both sexes. In women the proportion of suicides to female inhabitants may go as high as 21-22 per 100,000, while in males this ratio may be as high as 53-54 per 100,000. Suicide practically begins at the age of 10 years and increases in frequency with age, especially after the age of 40, when the increase is unbroken.—*Blätter für Vertrauensärzte der Lebensversicherung*, September-October, 1915.

Accident Insurance.—A policy insuring against injuries effected through external, violent, and accidental means alone is held in *Smith v. Travelers' Ins. Co.* L.R.A. 1915B, 872, not to cover death from meningitis resulting from a violent snuffing of a nasal douche, which caused infection to pass into the middle ear and thence through the mastoid into the brain, where the snuffing was no harder than was intended.

Book Reviews.

THE AMERICAN YEAR BOOK. A Record of Events and Progress, 1915. Edited by FRANCIS G. WICKWARE, B.A., B.Sc. With Cooperation of a Supervisory Board Representing National Learned Societies. New York and London: D. Appleton and Company, 1916.

THIS is the sixth issue of the American Year Book, which is intended for the needs of writers and searchers of every kind. The editor and his collaborators well act up to the intention, and have succeeded in compiling each year a book of ready reference of the greatest value. In particular it should be of use to scientific and medical men, as chemistry and physics, the biological sciences, anthropology and ethnology, psychology, and philosophy, and the medical sciences are all discussed briefly but adequately by authorities in the various departments. That part dealing with vital statistics is of especial value. The book supplies an excellent means of ready reference and should be on the desk of every writer.

AN INDEX OF TREATMENT, by Various Writers. Edited by ROBERT HUTCHISON, M.D., F.R.C.P., Physician to the London Hospital, and JAMES SHERREN, F.R.C.S., Surgeon to the London Hospital. Revised to Conform with American Usage by WARREN COLEMAN, M.D., Professor of Clinical Medicine and Applied Pharmacology, Cornell University Medical College. Seventh Edition. Price, \$7.00 net. New York: William Wood & Company, 1916.

IT is a sufficient proof of the popularity and usefulness of a work of this character to state that it has reached its seventh edition. The authors are all prominent members of the English medical profession, many with an international reputation. It is obviously impossible to present a detailed review of any work of this size, but it may be said that the great majority of the articles are eminently satisfactory, and in only a very few instances the more recent advances have failed of mention. Such omissions are that of the Baccelli treatment of tetanus and the intraspinal methods of medication in syphilis of the nervous system. The warning against the use of thyroid in the treatment of obesity seems inadequate. On the other hand, most of the articles are fully up to date and the book is provided with an extensive index which enhances its value considerably.

CONSUMPTION AND ITS CURE BY PHYSICAL EXERCISES. By FILIP SYLVAN, M.D. Price, \$1.25 net. New York: E. P. Dutton & Co., 1915.

THIS book, with two prefaces, one evidently intended for the public and the other in the form of an address "to medical men," contains a strange mixture of truths, misstatements, and dangerous advice. As an example we may quote the following from the general preface: "There is no getting away from the ugly fact that the majority of patients in the present sanatoria in practice actually become worse instead of better." In his preface "to medical men" the author makes the following modest statement: "We have to find out which gymnastic exercises can be performed by consumptives in various stages of the disease without causing any overstrain. This is what I claim to have discovered, and my results show that my claim is justified."

The first chapter is devoted to historical remarks and quotations from the works of Hutchinson, Villemin, Koch, Walters, and Bandler. The rest of the book is mainly devoted to Ling's gymnastic system, which the author considers the best preventative of tuberculosis and recommends also as the best treatment for pulmonary tuberculosis in all stages. Concerning tuberculin he makes the following statement: "The use of tuberculin ought to be prohibited altogether, because even in cases where tuberculin seems to reduce the tubercle bacilli it is of very little value, if any at all, and frequently does the patient actual harm." "The temperature as a guide for any treatment should be dispensed with." The author is opposed to rest treatment in bed in all cases of pulmonary tuberculosis in no matter what stage.

In the hands of a conscientious and discriminating physician the book might be of some value because of the instructive and interesting remarks on hydrotherapy and the descriptions of the various gymnastic movements. These are well worth considering as prophylactic means. In the hands of an untrained patient the book is likely to produce great harm. The author com-

mits the serious error of treating the tuberculous disease and the predisposition to it in the same manner. He forgets that the former is a pathological entity, the latter a physiological poverty.

THE WORK OF OUR HANDS. A Study of Occupations for Invalids. By HERBERT J. HALL, M.D., and MERTICE M. C. BUCK. Price, \$1.50 net. New York: Moffat, Yard & Company, 1915.

"A WAR that goes on year after year between the machine and the man, between disease and the man, keeps our ambulances busy and taxes our charities in no uncertain way. The hospitals do their best, our charitable organizations are very efficient, but there are thousands of men and women in every great city doomed to idleness and dependence because of injury or some illness that makes ordinary work out of the question." In this paragraph from the introduction to their book the authors aptly summarize the economic problem with respect to idleness enforced by disease or injury. In a series of most entertaining chapters they show that this problem is being attacked vigorously and with no uncertain results. The present struggle in Europe is bringing into sharp focus the necessity of adapting the crippled individual to some useful and congenial occupation, a necessity that has been met in isolated instances for many years past and during peaceful times. This necessity has existed, however, on a large scale in the case of those invalidated, but not disabled by heart disease, tuberculosis, insanity or other nervous disease, etc. In modern institutions for the care and treatment of patients suffering from these conditions the teaching of suitable occupations and keeping the patients engaged in them for definite periods every day, is an important item in the regular routine. But the subject is not merely one of economic importance. It is also one of profound therapeutic significance. Both aspects are discussed in this book by the authors, whose knowledge of their subject matter has been obtained at first hand and by actual experience in teaching new occupations to physically or mentally handicapped individuals. In Chapter I of the first part of the book they describe the workshops that have been established in general hospitals, notably in the Massachusetts General Hospital and in the recently erected Burke Foundation Convalescent Home at White Plains, N. Y. The succeeding chapters deal with the following subjects: manual work for patients in state and county hospitals; sanatorium treatment for people of small means; teacher and pupil; the trained nurse and the work cure; the well-to-do patient at work; the industrial problem of the "tubercular" (the word should be "tuberculous"); and handicapped labor and the law. Part II discusses the more technical aspects of occupational instruction for the handicapped, and the special application of this instruction in definite diseases. The following topics are dealt with: teaching of the handicapped, methods of teaching, readjustment, organic nervous diseases, hysteria, epilepsy, chorea, mental diseases, borderline cases, work with the aged, neurasthenia, psychasthenia, and work with cripples. The authors have written a volume that may be regarded as the first of its kind, at any rate in the English language, a volume that cannot fail to be of eminently practical value to both sociologist and physician.

THE CLINICS OF JOHN B. MURPHY, M.D., AT MERCY HOSPITAL, CHICAGO. Volume IV, Number 5. October, 1915. Octavo of 229 pages with 58 illustrations. Published bi-monthly. Price per year, paper, \$8.00 net; cloth, \$12.00 net. Philadelphia and London: W. B. Saunders Company, 1915.

THIS number is largely taken up by discussions based on clinical cases representing various types of bone lesions such as fractures, luxations, metastatic arthritis, tuberculosis of the knee-joint, painful stumps after amputations and contracture following joint infection. There are also several cases of malignant growths, among the most interesting of which is that of sarcoma of the ovary. Another interesting case report incorporated in this number of the Clinics is that of an inoperable recurrent carcinoma of the nasopharynx and other structures treated by mixed toxins with the disappearance of the tumor under five weeks of treatment, this case being reported by Dr. William B. Coley. There are also several cases bringing out points of interest in the surgery of the nerves and a few other topics. This number of the Clinics will appeal to those who are especially interested in bone surgery; to others it is apt to be somewhat disappointing.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held February 4, 1916.

Dr. JOHN DOUGLAS in the Chair.

Cases in Which Nail Extension Was Especially Indicated.—Dr. JOHN C. A. GERSTER presented two cases.

CASE I.—Malunion (Three Inches Shortening) of Six Months' Standing; Reestablishment of Fracture (Open Operation); Nail Extension; Result Nine Months Later. The patient was a boy, thirteen years old, who was admitted to Mount Sinai Hospital six months after a transverse fracture of the femur. Fusion had taken place and there was a shortening of three inches. Reestablishment of the fracture was made by the open method and nail union with extension of seventeen pounds was employed. Upon release the nail union did not shorten up, and the nail holes healed without giving any trouble. The boy now, nine months after the nail extension, had a shortening of only one-third of an inch and he wore an ambulant splint. Dr. Gerster thought that after about six years more of care the boy would have no trouble whatever.

CASE II.—Bilateral Fracture of Femoral Shaft; Extensive Abrasion; Compound Fracture of One Side. This patient was run over by an automobile and had very extensive abrasions from the waist down, involving both extremities, one of the worst cases of the kind Dr. Gerster had ever seen; the child was literally skinned all over. There was no sound skin except below the knees. X-ray plates were shown. It was out of the question to attempt to apply a plaster-of-Paris cast or any kind of extension because of these extensive abrasions. The accident occurred April 26, and on May 5 a fracture hematoma was found converted into pus which was incised and drained. On May 7 nail extension was done on both sides. The legs were suspended and kept at right angles to the thighs. May 28 distraction occurred, as shown on the plates. Dr. Gerster was away for two weeks and the extension was not interfered with during his absence, with the result that instead of shortening there was lengthening of about one-half an inch.

Dr. Gerster said he showed these two cases to illustrate the fact that there was a definite field for nail extension, a field in which such a procedure would serve a useful purpose. Previous to the introduction of nail extension not much could have been done with such cases as he had shown. The fractures all healed without sequestration.

Dr. L. MILLER KAHN said they had had at the Lebanon Hospital seventeen cases in which the nail extension was employed. In none of these could they have applied any other method of extension than the nail extension. The nail holes were not infected. In one case they used the nail in a compound fracture of the femur, contrary to the usual advice given. They had one case in which the nail hole persisted for four months.

Dr. LYLE showed pictures of one case of fracture in which there was three and a half inches shortening of three months' standing. In gunshot wounds of the bones nail extension was the method of choice but one should keep out of the diaphysis.

Dr. Gerster said that he had had thirty-five cases of nail extension and he had seen among these but one case of infection. In this instance the dressings were not on firmly enough and the child scratched himself and so carried the infection.

Fracture of Lower End of Radius with Anterior Dislocation of Ulna at the Wrist.—Dr. CHARLES E. FARR presented two cases which were exactly alike, both having fallen, and ordinary force caused the Colles' fractures. The deformity was rather exaggerated in both patients. In one case it required three attempts under nitrous oxid gas to reduce the fracture and it was three months before this patient could resume his work. The x-ray pictures were shown of both cases. These cases were supposed to be rare but Dr. Farr doubted it, for many cases were not reported at all.

Cases of Hemophilia, Purpura, and Severe Post-Hemorrhagic Anemia Treated by Blood Transfusion.—Dr. EDWARD W. PETERSON presented these patients.

CASE I.—This patient was a girl, six years of age, with

a diagnosis of purpura hemorrhagica fulminans. Her parents were alive and healthy. Her father had a severe nose bleed when a youth. The patient had had whooping cough; otherwise she had always been well until in May, 1913, when she fell, striking her nose. The injury was not severe but was followed by rather profuse epistaxis and ecchymoses on the nose and lower eyelids. After this she had frequent bleeding from the nose, but not requiring any special treatment. On May 21, 1915, there was a profuse epistaxis and vomiting of bright red blood. Dr. O'Connell, who was called in consultation with the family physician, was unable to check the flow. The anemia finally became so acute that the life of the child was threatened. She was sent to the Post-Graduate Hospital and on the way was thought to be dying. This was probably an attack of syncope. Without any preliminary tests, the mother acting as the donor, a transfusion of 325 c.c. was given. The resuscitation was immediate and it was very impressive to note the marked change in the patient's appearance. During the next three weeks there were frequent small hemorrhages from the nose, also from the gums, the left ear, intestines, and vagina. There was also blood in the stools and in the urine. Two more transfusions were necessary before the bleeding tendency was corrected, a foreign donor being selected. The bleeding tendency did not manifest itself then for over a year. At the present time she was showing again a slight tendency to bleed. On December 31, 1915, the bleeding time was prolonged. The platelets were 36,000, the leucocytes 13,000, the plasma coagulation twenty-two minutes, the capillary resistance was XXXX and pressure 130.

CASE II.—This patient was a girl, eleven years of age, with a diagnosis of Henoch's purpura, nephritis, and secondary anemia. She was a patient of Dr. Lorber. Her chief symptoms were abdominal pain and those accompanying post-hemorrhagic anemia. There was blood in the urine and in the stools. There were purpuric spots on the body. She had convulsions and had been ill for two months. Following a transfusion of 270 c.c. of blood, the father being the donor, there was a wonderful hematopoietic stimulation with a cessation of the bleeding. The later results showed the blood picture much improved; there was no further bleeding and recovery had followed.

CASE III.—This patient was a boy, eleven years of age, a patient of Drs. Chace and Barrett. The chief symptoms were abdominal pain, rectal bleeding, purpuric rash, and ecchymotic spots on the limbs. The diagnosis was Henoch's purpura. The treatment consisted in transfusion of 200 c.c. of blood. Forty c.c. were given intramuscularly from a professional donor. This was followed by an immediate improvement, the bleeding stopping. The later observations showed this patient to be in excellent health and with no recurrence of the symptoms.

Treatment of Colles' Fracture Considered from the Standpoint of Muscle Physiology.—Dr. ALFRED J. BROWN read this paper, in which he discussed the basic principles with regard to the causation and retention of deformity on the one hand and the mechanics of reduction and immobilization of fracture on the other, and applied these principles to Colles' fracture. In any fracture, aside from those which were impacted, the position of the fragments was determined in part by the direction of the fracture line, slightly by the direction of the causative force, and much more by the action of overstimulated muscle upon the fragments themselves. In consequence it was of the utmost importance to consider the various movements in all directions which the fragments might execute, the site of the fracture acting as a fulcrum around which the movements took place. At all times the action of the muscles upon the fragments must be carefully studied in the light of the abnormal fulcrum around which motion took place and the final position in which the part was immobilized must be governed entirely by these considerations. The problem of treatment therefore resolved itself into restoring bone continuity by bringing the fractured ends into apposition and placing the limb in such a position that equilibrium would be restored if possible between opposing groups of muscles to the end that the fragments might more readily be restored to the anatomical and physiological norm. In illustration of these points the writer described the mechanics involved in fractures of the greater tuberosity of the humerus, fractures of the radius at the junction of the upper and middle third, and the displacement of the shaft of a bone upon the

head and neck, as in fracture of the neck of the femur. The fracture of the radius, known as Colles' fracture, offered a similar problem and when studied in the light of muscle physiology fell into the class in which the smaller fragment was separated from the shaft and was controlled, for all practical purposes, by one set of muscles only. After referring to the theories in reference to the etiology of Colles' fracture, the essayist said it was very probable that both the "*arrachement*" or tearing through hypertension and the force directed obliquely upward and backward were instrumental in the production of the fracture. In the majority of cases in which displacement was present, the line of fracture ran from below upward and backward, and from within, that was, from the ulnar side of the bone, outward and slightly upward. In addition the continuation of the vertical force impacted the posterior portion of the upper fragment and resulted in a tilting upward and backward of the lower fragment through the transverse axis. The vertical diameter of the anterior portion of the lower fragment was therefore slightly shortened because of the compression of tissue due to the impaction and the same was true of the posterior vertical diameter of the upper fragment, usually to a somewhat greater extent. Upon reduction of the fracture there existed in consequence a gap between the anterior and posterior margins of the bones and the two fractured surfaces were convex and in contact only at their points of greatest curvature. This predisposed the fragments to tilt upon one another, the direction of the tilting being governed by the direction of the pull of the stronger set of muscles governing the fragments. A study of the anatomy and physiology of the muscles of the forearm and wrist showed that the tendency of all muscles passing over the wrist joint was to exert a strain on the lower extremity of the radius which tended to force this portion of the bone backward and toward the radial side of the forearm. When a fracture separating the lower extremity of the bone from the shaft was present, the tendency of the muscles, because of the induced spasm, was to increase the deformity and after reduction of the fragments predisposed to recurrence. As a consequence of the problems presented by fractures of this kind the result of treatment had been unsatisfactory, both from a functional and cosmetic standpoint. The proof of this statement lay in the records of the law courts, for, with the exception of Pott's fracture, Colles' fracture was more commonly the cause of a law suit than any other. Inasmuch as the muscles acting most forcibly on the lower fragment, drawing it backward and rotating it outward on its long axis, were situated upon the dorsal and radial side of the extremity, it seemed that the indication was to shorten these muscles to their physiological limit and thus minimize the upward and backward pull on the fragment and at the same time offer an antagonistic muscle pull through the brachioradialis, which in the position of supination of the forearm became a pronator and thus tended to pull the lower fragment forward, rotating it from behind forward around its vertical axis. To ascertain the amount of shortening obtainable by this posture of the forearm, measurements were made of the forearm of adults who had never had a fracture. As a result of their observations the following method had been adopted during the past eight months at Bellevue Hospital in the treatment of Colles' fractures: The patients had been anesthetized to the stage of primary anesthesia, nitrous oxide gas being used in the majority of cases, and the impaction, if present, had been completely broken up in the following manner: The hand of the operator, the palm of which corresponded to that of the injured wrist, grasped the hand as in shaking hands. The hand and wrist were then hyperextended as far as possible, thus loosening the anterior portion of the fragments and increasing the deformity. The other hand of the operator then grasped the forearm at its lower portion just above the line of fracture. Traction and counter traction were then applied, the hand of the patient being drawn into a position of marked ulnar abduction and at the same time the upper hand of the operator supinated the upper portion of the forearm while the lower hand slightly pronated the lower fragment. It might be necessary at times to assist the pronation by pressure with the thumb upon the lower extremity of the radius. This manipulation was carried out two or three times in order to completely break up impaction and assure complete reduction. At the end of the manipulation the upper forearm was in complete supination with the lower fragment slightly pro-

nated upon it, and in this position with the forearm flexed to 90° upon the arm anteroposterior moulded plaster-of-Paris splints extending from the tip of the fingers to a point half way between the elbow and shoulder were applied. It was essential that the splints include and extend above the elbow, for in this way only could the movements of pronation and supination be interdicted. At the end of one week the splints were removed and the site of the fracture examined, the distal portions of the splint were shortened to the metacarpalphalangeal articulations and movements of the fingers encouraged. At the end of the second week the proximal portions of the splints were removed to a point just distal to the elbow, and at the end of the third week the splints were removed entirely and the forearm carried in a sling during the fourth week, at the end of which time in the majority of cases full function had been established; by the end of the fifth week many patients had been able to return to work. In the hands of the writer this method had afforded better results with less protracted convalescence than any other method heretofore employed.

Result of Section or Irritation of Pneumogastric in Operations about the Neck.—Dr. ASPINWALL JUDD presented this communication in which he stated that he reported these cases because of the conflicting testimony as to the results of section or irritation of the pneumogastric and in the hope of bringing out a discussion that would clear the atmosphere. From a study of the literature and of his own cases he is impressed with the idea that many symptoms recorded as the result of this section or irritation might be incidental, that was, they might be the result of complicating factors caused by the original disease or by the operation. As in practically all the cases reported in the literature the section was the result of an accident occurring during the course of an operation for the relief of some diseased condition, some of the resulting symptoms, differing in the different cases, might have been caused either by the original disease, the anesthetic, shock, hemorrhage, etc., alone or plus the section of the vagus. He was inclined to agree with Park that an immediate fatal result was not to be apprehended, provided proper precautions against shock were taken, that pneumonia was the result of a complication due to faulty anesthesia or failure to prevent aspiration of mucus or blood during the first twenty-four hours after operation, and that the lung complications, except such as were known to be the result of vagus section, were due to the same cause and could be avoided. Dr. Judd reported four cases which, though too few to justify conclusions, emphasize the fact that section or irritation of the vagus seemed to him far less dangerous than they had been led to suppose.

CASE I.—This patient was a man 55 years of age and in excellent condition, operated upon by the writer for carcinoma of the thyroid gland. This patient had been exhibited before the Academy of Medicine on several occasions extending over a period of two years. The operation consisted of an entire extirpation of the thyroid and accompanying glands on the right side. In the course of the operation, in order to remove all the malignant growth it became necessary to resect the pneumogastric. The immediate result was a rise in pulse rate which persisted for several days, and gradually subsided month by month, until at the end of a year it was normal. There was no change in the blood pressure and no symptoms referable to shock were noted at any time. The patient suffered with slight dyspnea for a few days and from a partial aphonia for about three months. He had remained well until he disappeared from the writer's notice more than two years after the operation.

CASE II.—This patient was a young man, 25 years of age, operated upon for an enormous hypertrophic thyroid. Before operation he had all the symptoms of thyroid poisoning. After having been treated in the hospital for four weeks without result, he insisted upon an operation, though told that he would probably die on the operating table. The writer removed the entire thyroid gland, during which operation an artery clamp was fastened to the pneumogastric accidentally and remained in place about three-quarters of an hour. This man collapsed on the table, but was revived by the use of saline infusion and stimulants. The man's pulse remained very rapid for forty-eight hours, but within one week had sunk to 60, where it remained for nearly two weeks, except when influenced by drugs. His aphonia was absolute but gradually improved until, at the present time, while his voice was husky, it was

otherwise unimpaired. He suffered with cough, a moderate amount of dyspnea, and a pneumonia involving the lower lobe of the lung. Evidence of consolidation persisted for several months after his discharge from the hospital. No gastrointestinal symptoms were observed.

CASE III.—This patient, 39 years of age, gave a family history of tuberculosis. He was exceptionally strong. Six years before he was ill for a year from a condition which was finally diagnosed as typhoid fever and which was followed by pyelitis. While he was convalescing his cervical glands on both sides began to enlarge. A diagnosis of tuberculous glandular involvement was made. Treatment with the x-ray seemed to help him for a while, but later the glands began to grow again, accompanied by an extension of the process into the chest. Pressure on the trachea and great vessels became so marked that operation was decided upon. In a fairly extensive operation on the right side most of the glands were removed; in attempting the removal of the deep glands on the left side, the internal jugular, the carotid, and the pneumogastric came away *en masse*, the tissues being so friable that it was almost impossible to finally secure them by means of ligature. By efforts at infusion, transfusion, tying off of arms and legs, and stimulants, the patient finally pulled through. Before operation the hemoglobin was 100; after operation, 40 per cent., but it rose within a few months to normal. There was no leucocytosis or lymphocytosis observed in this case at any time. Immediately after operation the patient's pulse rose to 140 and remained so for a number of days, finally dropping to 120, where it remained for over a year. The aphonia, which was partial before operation, became complete. A harsh dry cough with scanty expectoration was very persistent. A year after the first operation a second operation for recurrence was followed by apparently complete recovery. The pulse rate upon exertion remained about 120, but when the patient was quiescent sank into the nineties. The dyspnea on exertion and the cough remained. Two years after the second operation the patient again presented symptoms of recurrence. During this time high frequency electricity to the cervical region resulted in a gradual diminution of his aphonia. He suffered from pain in the chest, muscular weakness, tachycardia, and diarrhea, and began to have a series of attacks accompanied by an alarming increase in blood pressure to 200 or more, rapid pulse to 140, purpling of the skin, and edema of the lungs. These attacks promptly subsided under the influence of atropine 1/100 of a grain, and morphine 1/4 of a grain. They were finally controlled by 60 grains of bromide at bedtime. The patient died in a heart attack.

CASE IV.—This patient, 60 years of age, was operated upon for a very extensive carcinoma of the tongue involving all the glands on the left side of the neck. During the operation it was found necessary to resect the internal jugular, the common carotid, and the pneumogastric. The patient collapsed on the table, but was revived by saline infusion and stimulation. The pulse rose to 120, but gradually subsided, until at the present time, ten days after operation, it was 100, respiration 20, and temperature normal. At no time had this patient suffered from dyspnea, and there were no changes in the lung in spite of the fact that the tracheotomy tube was inserted and that he had extreme difficulty in swallowing. In spite of the absence of the tongue, this patient did not suffer from complete aphonia. He had had no gastrointestinal symptoms and in common with three of the four patients had suffered from no muscular weakness.

Dr. EDWIN BEER asked regarding the symptoms that followed the section of the vagus in the cases he reported. So far as symptoms of vagus irritation was concerned, he had seen one instance lately in which the vagus was divided in the chest and there were absolutely no symptoms of vagus irritation or paralysis to be noted.

Dr. JUDD said that two out of the four cases reported developed pneumonia, the other two not showing any signs of pneumonia whatsoever. All had tachycardia which persisted at least one year except one case in which they took out the thyroid. Cough, dyspnea, and acceleration of the heart beat were present in all the cases. Aphonia was present, but tended to disappear on stimulation of the vagus on the opposite side.

Blood Transfusion in the Treatment of Severe Post-Hemorrhagic Anemia and the Hemorrhagic Diseases.—Dr. EDWARD W. PETERSON presented this paper in which

he stated that most of the articles on blood transfusion, with a few notable exceptions, dealt largely with the question of the operative technique, gave a wide field of indications, but were lacking in recording the results obtained. The majority of transfusion workers were over-enthusiastic and were using the procedure without proper discrimination as to indications; on-lookers, viewing the work in unwisely selected cases, were inclined to underestimate its true worth. As Hartwell had pointed out transfusion of blood from one individual to another should be considered as hemogenous transplantation of living tissue, and not merely as the transfer of a chemical or physical mixture. After a transfusion the patient's blood would show an increase in the number of red cells, a rise in hemoglobin percentage, and a decrease in coagulation time. There was increasing evidence that the whole blood was hemostatic, hemopoietic, and in selected instances, antitoxic and bactericidal. It was indicated then in (1) hemorrhage of various types and degrees, (2) in selected cases of anemia, both primary and secondary, not due to hemorrhage, (3) and in selected toxic and septic conditions. Dr. Peterson stated that at the present time he would consider only the first group, recording the results obtained by blood therapy in 27 cases of simple pathological hemorrhage. Thirty-four transfusions were given in 23 cases in this series; 4 cases were treated by intramuscular injections of blood. In acute and chronic post-hemorrhagic anemia, no other remedy would compare in efficiency with whole blood in producing hematopoietic stimulation. In the acute variety (following trauma, labor, operation, or accidental cause, or as complication of ectopic pregnancy, gastric or duodenal ulcer, typhoid fever, etc.) a single large transfusion was indicated, while in the chronic type (that resulting from repeated small losses of blood) better results were obtained by giving serial transfusions of small or moderate amounts of blood. There were seven cases of acute and four of chronic post-hemorrhagic anemia transfused. The histories in most of these cases left no doubt as to the striking effects of the blood transfusion. In discussing pathological hemorrhage the essayist first considered hemophilia. He stated that this condition might often be controlled by the injection of whole blood or serum, but in obstinate and intractable cases the indications were best met by transfusion. While the disease itself was not cured, the alarming and dangerous symptom was controlled and immunity against excessive bleeding was established for a variable period. Prophylactic injections of blood should be administered from time to time, for as age advanced the bleeding tendency diminished, and might cease altogether at maturity. There were five cases of hemophilia in this series, in all of which the transfusion was effective. Hemorrhagia neonatorum probably belonged to the purpuric group, and was dependent upon some form of toxemia. Under all circumstances it was a serious affection with a bad prognosis. The serum treatment of Welch, the intramuscular injection of whole blood, and blood transfusion had been attended by brilliant results and the mortality had been reduced from 50 to 75 per cent. to 5 or 10 per cent. According to the experience of Lespinasse of Chicago and Green of Boston, blood transfusion was the method of choice and would often prove life-saving after the failure of all other methods. The essayist reviewed the case in which the first transfusion for hemorrhagia neonatorum was done, reported in the MEDICAL RECORD, May 30, 1908, by S. W. Lambert, in which the infant apparently in a dying condition passed immediately after transfusion to a state of perfect health with no period of convalescence. His own experience in this condition was limited to one case in which after the hemorrhage started the child became decidedly jaundiced. In this instance the transfusion was followed by an improvement in the general condition of the child and a lessening of the jaundice, but some days after removal from the hospital the infant died. This case was reported simply to show the prompt hemostatic effect of transfusion and to call attention to the fact that the introduction of blood into the superior longitudinal sinus through the anterior fontanelle offered an easy method of transfusion in the newly born. Symptomatic and idiopathic purpura also belonged to the purpuric group. In the symptomatic variety, if the underlying etiological factor could be determined and eliminated, the disease would tend toward a spontaneous and permanent recovery. On the other hand idiopathic purpura or "pseudohemophilia" or "essential thrombopeny" was a clinical entity. Its mortality was fully 25 per cent. To this group belonged

eight cases of the series under consideration. Seven cases were given twelve transfusions. In addition to the transfusions, several were given blood intramuscularly. There were two deaths in the series, one due to acute nephritis occurring several months after the last transfusion, and the second occurring in a woman 63 years of age, who had been ill for months with purpura hemorrhagica. When brought to the hospital during a fulminating exacerbation, she was moribund. In three severe cases a simple transfusion corrected the bleeding tendency and apparently cured the condition, there having been no relapse up to the present time. In two cases in which hemorrhage was active and life was threatened from acute anemia transfusions tided the patients over the emergency period. Secondary hemorrhagic disease probably included all types of pathological hemorrhage, except hemophilia and constitutional purpura, and the term hemorrhagic was merely used for convenience to denote the variety of hemorrhage seen in icterus, sepsis, nephritis, blood diseases, etc. In the management of this form of bleeding it was imperative that, while carrying out measures for the control of the bleeding, the original disease be given proper treatment. The essayist reported two cases belonging to this group, one of chronic nephritis with persistent epistaxis and one of severe anemia aggravated by frequent small nose bleeds. For the most part in this entire series the results of transfusion had been good, in but few cases ineffectual, and in none harmful. In certain instances in which the blood of the donor had proved disappointing the selection of another donor had brought about strikingly brilliant response. The best clinical results in his experience had been obtained in hemorrhagic disease, when a young healthy donor, not fully matured, could be secured. In the future a qualitative as well as a quantitative study of the blood would be the guide in the selection of a donor in a given case. One whose blood was rich in platelets, both qualitatively and quantitatively, should be chosen. In conclusion Dr. Peterson said that the transfusion of blood, intramuscular injections of whole blood, and intravenous or intramuscular injections of homologous serum were the most efficient measures and were of value, in the order named, in the treatment of hemorrhage and hemorrhagic diseases.

Dr. ALFRED FABIAN HESS said that practically there was no class of diseases about which there was so much confusion as hemorrhagic diseases, and there was a great opportunity for the surgeon to help in studying the conditions presented. Dr. Peterson was one of the first surgeons to study these cases from the laboratory standpoint. Although these cases could not be divided carefully, they could make a larger distinction between hemophilia and purpura. At least these two groups of bleeders could be distinguished. It would be of great advantage if all surgeons who saw these cases would report them. Dr. Hess said that too much stress was laid upon the coagulation time. The coagulation time of the blood was one of the most important things that the surgeon wanted from his standpoint. The coagulation of the blood was only effective in hereditary hemophilia. The surgeon might be led astray if he considered the coagulation time of the blood in purpura because it was so often normal. With regard to treatment, there practically was no treatment for these diseases. Perhaps a small transfusion might be of some value according to the report of Libman and Ottenberg, but Dr. Hess did not think so. This method was an emergency therapeutic measure. In the local treatment thromboplastin, made from brain tissue and the active principle which was a lipoid substance in the brain, made by the Department of Health, was of value. This was particularly efficacious when used in bleeding from the mouth after an extraction of a tooth, or from the rectum, and it was especially valuable in bleeding occurring in myelogenous leucemia. Dr. Hess believed in the local use of thromboplastin, especially in bleeding from parenchymatous tissues. It was also of value in prostatic bleeding and in nasal hemorrhages which occurred in diphtheria, such as were met with so often at the Willard Parker Hospital. It was also efficacious in gastric hemorrhages.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held January 25, 1916.

DR. GEO. W. KOSMAK IN THE CHAIR.

Sarcoma of the Ovary Complicating the Puerperium.—Dr. GEORGE L. BRODHEAD reported this case. He said the patient was 18 years of age, and presented herself

at the prenatal clinic of the Harlem Hospital on September 9, 1915. The history was negative and nothing abnormal was found in the abdominal examination. On October 25, 1915, she was delivered at term, normally, of a living child. On the day following her delivery her condition was good and temperature 100.5° F. On the second day the temperature was 101.4°, pulse 96, and she made no complaint. On the third day the temperature rose to 102.5°, the pulse was 132, and she complained of pain and tenderness in the abdomen. The left side of the abdomen was soft and slightly tender, but there was marked tenderness and rigidity in the right inguinal and lumbar regions and in the epigastric and upper umbilical regions. The leucocytes were 17,000, the polynuclear count 88 per cent., lymphocytes 12 per cent. On the fourth day, the temperature rose to 103.2°, pulse 130, the tenderness and rigidity increased, and the vaginal examination showed some tenderness in the fornices. For the next week, until the day of operation, the temperature varied from 101° to 103°, and after the operation remained normal. Eight days after delivery a mass could be palpated in the right lower quadrant, tender, elastic, and slightly movable, and a diagnosis of abdominal tumor was made. The blood count then showed leucocytes 21,000, polynuclears 74 per cent. and the urine showed a faint trace of albumen and there was a positive glucose reaction. The patient was transferred to the service of Dr. Haynes, who performed a laparotomy and found a sarcoma of the right ovary measuring 15 x 8 x 6 cm., bluish in color, with greatly dilated veins. The patient made an uninterrupted recovery and left the hospital in good condition. Dr. Gonzales, the pathologist, reported that the specimen was a spindle celled sarcoma.

Cesarean Section for Uterine Inertia and Contracted Pelvis.—Dr. BRODHEAD reported this case. The patient was 28 years of age, married, and became pregnant for the first time about February 1, 1915. She was a strong, healthy woman. The external measurements were, spines, 23, crests, 27.5 cm.; the transverse at the outlet was 8 cm., and the promontory could not be felt. Labor was estimated for about November 1, 1915. On November 13 labor began at 8 P. M., positive R. O. A., head above the brim. On November 15, at 9 A. M., the cervix was thin and admitted one finger; the pains were irregular, and the vertex was still above the inlet; the cervix admitted two fingers and the patient was discouraged, having had pains for 86 hours. The membranes were intact and the fetal heart was strong. A careful examination showed a moderately large head floating above the brim, and a moderately contracted pelvic inlet. Under the circumstances, the uterine inertia being marked, it was deemed advisable to perform cesarean section. This was done and a living child weighing 7¾ pounds was extracted. The recovery was uneventful, the mother and child leaving the hospital in excellent condition.

Vaginal Cesarean Section for Blighted Ovum.—Dr. BRODHEAD reported this case. The woman was 19 years old, married since March, 1915, and had her last menstruation on March 27. About July 1, she began to bleed and was treated for threatened abortion. The bleeding continued for about eight weeks, when it ceased. The family physician sent her to Dr. Brodhead on November 19 with the statement that the uterus had not enlarged since July. Upon examination the uterus was apparently enlarged to the size of a three months' pregnancy and the patient was informed that in all probability the pregnancy had proceeded normally until about July 1, when the fetus died and the uterus had been unable to expell the blighted ovum. The patient consented to operation, and a vaginal cesarean section was done. A placenta of about three months' development was removed; the fetal sac was distinct, but no trace of the fetus could be found, absorption having taken place. The condition, while rare, was met with frequently enough to make them guarded in the prognosis of a supposed threatened abortion; for, while bleeding might entirely cease and the patient feel perfectly well again, the uterus would not increase in size, and sooner or later would be emptied of the blighted ovum.

Dr. HENRY DAWSON FURNESS reported the case of a woman who had missed four menstrual periods. On examination the uterus was found to be enlarged to a three months' size. There was no bleeding whatever. She aborted and the placenta was found to be as large as a goose's egg and the fetus less than one inch long and attached by the cord to the placenta.

Dr. HOWARD C. TAYLOR asked Dr. Brodhead if there

was no fetus found, was it therefore absorbed? Could a fetus be absorbed in the interior of the uterus?

Dr. BRODHEAD replied that this was his impression as he had seen a number of blighted ova of various periods of development with no trace of the fetus and many of those patients had been very carefully observed. In this instance the sac was intact and there was quite a little fluid present, but the fetus, of course, might have escaped.

Dr. ALFRED M. HELLMAN said that he had a similar case to the last one reported by Dr. Brodhead. The patient had one profuse hemorrhage and complained of cramp-like pains at night. There was no dilatation of the cervix. Although she was six months pregnant, the uterus was the size of a four months' pregnancy. He doubted the history given. She was observed for one week or ten days and then sent home. Ten days later she returned, stating that her pains were worse and that there was a slight discharge slightly stained with blood. He again examined her and found no apparent change and no cervical dilatation and she was sent home for another week. She was watched for five weeks in all and still there was no increase in the size of the uterus, knowing that she was pregnant and that the fetus must be dead, he introduced two rectal bougies and packed the cervix and vagina with gauze for thirty-six hours, when she delivered herself of a good sized placenta undergoing cystic degeneration. The placenta looked like a multitude of small parovarian cysts.

Dr. HERMANN J. BOLDT said he had seen many cases where the ovum had advanced to two or three months and yet he could find no trace of the fetus at all. The size of the placenta corresponded to a two or three months' pregnancy.

Dr. BROOKS H. WELLS said he had seen several cases in which the sac was apparently intact and yet no fetus could be demonstrated, and he took the ground that the fetus had died in the early stages, and "melted away," as it were. One might get an intact sac and yet find no trace of a fetus.

Dr. FRANCIS WARD LANGSTROTH, Jr., of Ridgefield Park, N. J., reported the case of a woman who had the most profuse hemorrhage he had seen in years, the blood filling two or three vessels. He dilated the cervix under general anesthesia. The cervix was closed, not dilated at all, and it did not seem that anything could come away except blood. He found a large amount of placental tissue, but could not find any fetus at all. The miscarriage was at the third month estimation, according to her last period. The very profuse hemorrhage came on suddenly after only a slight show the preceding night.

Dr. GEO. W. KOSMAK said that very often malignant growths in the ovary could not be diagnosed by their symptoms and in most cases the diagnosis was not made until the pathological report of the excised ovary was received. In one of his cases what was believed to be a cystic ovary was removed during the course of a laparotomy and the subsequent pathological examination showed it to be carcinomatous. The patient had been under observation for almost two years and no recurrences had been noted. It had been claimed that in every instance where malignant disease of one ovary was present, the other should be simultaneously removed, even if not apparently involved. Dr. Kosmak believed that in view of his experience he would hesitate to follow this procedure.

Dr. HOWARD C. TAYLOR believed that in such cases, especially where the woman was anxious to have children, she would prefer to take the risk and not sacrifice the other ovary.

Early Results in a Case of Carcinoma of the Cervix Uteri: Presentation of the Patient and Specimen.—Dr. JAMES A. CORSCADEN presented this patient and the results of the operation to which she had been subjected were told by the Committee appointed by the Chairman (see below).

Dr. F. C. HOLDEN said that he had the pleasure and privilege of being one of Dr. John Byrne's House Surgeons and he had become very enthusiastic about his work. He said he was thoroughly in accord with the recent writing of Dr. Boldt to the effect that the only advantage the Percy method had over that of Byrne was in that the abdomen was opened by the former. Dr. Byrne labored under many disadvantages in that his work was done in the pre-antiseptic age when the opening of the abdomen was of a great deal more magnitude than it was today. He was of a very inventive turn of mind and the instruments and batteries used

by him were of his own design. The battery was of a liquid type and it was necessary to constantly agitate the fluid while it was being used to insure sufficient heat. Dr. Byrne never used a bright red heat on either the cautery knife or dome, but always worked for a dull red heat. At the Greenpoint Hospital they recently had a case of extensive carcinoma of the cervix which seemed suitable for the Percy operation. Both tubes and ovaries were removed and both the internal iliacs were ligated with heavy silk ligatures. This was followed by a long, slow application of the cautery as advised by Percy. When this case was examined two weeks later it was discovered that there was still carcinomatous tissue remaining. Four weeks after the first operation the abdomen was again opened and it was interesting to note that the iliac arteries were still closed completely below the ligated points. Again slow cautery application was made, and up to the present time this patient had shown a decided improvement in her general condition. Dr. Byrne's work was very frequently followed by extensive hemorrhage at the time of operation, and Dr. Holden felt that inasmuch as the abdomen was opened in conjunction with the Percy method it was advisable always to ligate the internal iliac.

Dr. HERMANN J. BOLDT said that he knew nothing that was superior to the treatment devised by Byrne and he believed that all the credit for this method of treatment of cancer of the uterus was due to Byrne. Percy had given them a method by opening the abdomen, which enabled them, however, to make use of a more thorough procedure. That was true, but to claims of superiority of the low grade over the high grade heat was, in his opinion, a myth. The high grade of heat would penetrate as far as the low grade. When one used the degree of heat Byrne did, the work could be done more rapidly and it was as safe as the low degree of heat if the abdomen was opened, so that the electrode could be controlled.

Report of the Committee on the Patient Presented by Dr. Corscaden.—Dr. HOWARD C. TAYLOR said that the results of the operation to him seemed to be very good. The usual circular scar was present and the parts were soft, with no inundation. On the finger after examination was found a slight amount of blood, showing that probably there was a return of the disease. He felt that if they could always get as good a result in these cases as in the one he just examined, the operation would be a very valuable one. The Percy operation differed from the Byrne operation only in that he opened the abdomen and in the degree of heat employed. Both Byrne and Percy laid great stress upon employing a low grade of heat. Outside of the mere opening the abdomen Dr. Taylor did not think the method of Percy differed from that of Byrne.

Dr. FREDERICK C. HOLDEN asked Dr. Taylor what he would do with such a case now.

Dr. TAYLOR replied that he would let it alone.

Dr. BROOKS H. WELLS said that the patient had a rather smooth funnel-shaped vagina and at the upper end about the small scar was a small area of infiltration, which gave the impression that the carcinoma was still making an extensive progression. Certainly as a palliative measure the operation had been a successful one. The question came up, however, what were they going to do with these patients who began to bleed again? Dr. Wells believed that in this case the bleeding would return in two or three months. In these inoperable cases he said he found acetone applied to the parts gave great relief, stopping the bleeding, partly controlling the sepsis, and destroying the odor. The patients improved greatly, gaining in color and in strength and this improvement lasted over a long period of time.

Dr. GEORGE H. MALLETT said that there were three methods of treating these cases, first, open the abdomen and do as Percy did and apply the heat again; second, use radium, and third, the application of the x-ray. By any of these methods the terminal stage would be postponed and the patient have months or years of comfort. Remarkable statistics had been given following the use of radium in these cases.

Dr. CORSCADEN said that the result of Dr. Taylor's examination showed the condition of the woman to be practically the same as it was three weeks after the operation. Whether the condition had really changed very much he was unable to say. She had been given x-ray exposures to the abdomen for the affected glands and whether these had anything to do with keeping it quiescent or not, he did not know. He said

he was waiting for any sign of increase in the growth before undertaking further steps.

Mortality Following the Percy Operation, with Report of a Case and the Autopsy Findings.—Dr. FREDERICK W. BANCROFT read this paper. He said that much had been written during the last decade upon the susceptibility of carcinoma and sarcoma to a low degree of heat. In 1912, Percy published his report in regard to carcinoma of the cervix and uterus by low temperature cauterization and he based his operation upon the premises, first, that a low grade of heat, above 45° to 50° C. would kill carcinoma tissue, while living connective tissue and muscular tissue would survive; secondly, that low degree of heat would penetrate much farther than high. His first premise he assumed from a study of the experimental work of Haaland, Clowes, and Loeb. His second premise was deduced from experimental results obtained on pieces of dead beef. Percy found that with a very hot iron carbonization of the surrounding tissues occurred, preventing heat conduction, and that coagulation occurred only for a distance of one-half an inch from the iron. On the other hand, with a low grade of heat, coagulation occurred for a distance of two and a half inches in all directions from the cautery iron. He had devised a cautery which was attached to a rheostat so that he was able to control the heat in the iron. Boldt had published a report of an autopsy of a case that died eight days after the Percy operation, the cause of death being general peritonitis. He stated that there were numerous viable cancerous cells present in the uterine wall. Boldt concluded that there was no evidence that low grades of heat were more efficacious than high temperature cauterization. Dr. Bancroft reported a case in detail. The main facts concerning the findings from the microscopical examination might be summarized as follows: Certain islands of cancer cells showed advanced degenerative changes, reaching in many instances stages of necrosis and dissolution. Others showed milder grades of degeneration, and still others had apparently been affected by the treatment. The intervening structures (the musculature and connective tissue surrounding the islands of cancer cells) had not wholly escaped injury. Dr. Bancroft said that many factors must be considered in the case reported by him, such as (1) the difficulty of determining the viability of the cells by their microscopical appearance; (2) the uncertainty of knowing the exact temperature of the cautery, and (3) the influence exerted by infection must be considered.

The Radical Abdominal Operation for Carcinoma of the Uterus.—Dr. HOWARD CANNING TAYLOR read this paper. He said that if they excepted certain superficial growths of a low degree of malignancy, there was no cure for cancer which was accepted by the profession other than its complete removal by surgical means. Though there had been promising results from the use of other agents, such as radium, x-rays, and the cautery, these results were not such that their use would be advised for a limited growth in a patient constitutionally suited for an operation for its removal. Personally he believed there was a distinct value in the use of radium, x-rays, and the cautery in cancer of the uterus. Their use was still experimental and sufficient time had not yet elapsed to prove the permanency of the results reported. The number of the cases treated by these agents that would remain cured beyond the five-year limit was uncertain and until more definite clinical statistics were available their use would be largely limited to the inoperable cases, and the earlier cases would be treated by some surgical operation for the removal of the growth. The surgical removal of cancer was a mode of treatment about which they had definite knowledge, and it was not to be abandoned until they had something that was certainly better with which to replace it. There was no doubt that the use of radium and x-rays had modified the selection of cases suitable for operation. The abdominal route rather than the vaginal was the first choice of most operators. There were certain cases, however, that were approached more easily through the vagina than through the abdomen on account of the size of the vagina and the thickness of the abdominal wall. A fat abdominal wall added greatly to the difficulty of any abdominal operation and was a contraindication for a radical abdominal hysterectomy. If there was a combination of thick abdominal wall and a wide vaginal with a prolapsed uterus, the vaginal route should be selected. Personally he preferred the abdominal route for all cases except those in which there was a fat

abdominal wall and a wide vagina. Dr. Taylor asked what was the difference between a simple and radical abdominal hysterectomy for carcinoma of the uterus. Theoretically there was a great difference, practically one merged into the other. In one operation vessels were ligated close to the uterus and no attempt was made to remove any of the pelvic connective tissue; in the other operation the ureters were exposed, the vessels were ligated outside of the ureters close to the pelvic wall and a large amount of pelvic connective tissue and a large portion of the vagina were removed. In favorable cases the theoretical radical abdominal hysterectomy could be performed and a large amount of pelvic connective tissue and the vagina removed. This added greatly to the chances of a permanent cure of the case. There was no doubt, however, that any series of radical abdominal hysterectomies contained cases that did not differ in the amount of tissue removed from cases in a series of simple hysterectomies by the same operator. The extent of the operation performed for the removal of any malignant growth was limited by two factors, the risk to the life and the amount of mutilation of the patient. In the radical operation there was a distinct risk to the patient. It was a more extensive operation requiring more time, complications during and after the operation were more frequent, and a higher primary mortality was a necessary result. The higher primary mortality of the radical operation was not due entirely to the operation itself. For a simple hysterectomy the growth must practically be limited to the uterus itself, while a considerable involvement of the broad ligaments was not an absolute contraindication to the radical operation. For growth of the same extent in patients in whom the radical operation was not contraindicated because of constitutional disease or a thick abdominal wall, Dr. Taylor believed that the primary operative risk was only moderately greater for the radical than for the simple hysterectomy and was not sufficient to outweigh the advantages of the more extended operation. After the ureters had been isolated the radical operation could often be done with little more difficulty than a simple hysterectomy. In his own cases the primary mortality was about 15 per cent. He believed the mortality would be less in the future with a more careful selection of cases. The injuries to the ureters were accidental division, ligation, and sloughing. He did not believe that the ureters were accidentally divided or ligated as frequently in the radical as in the simple hysterectomy, and it was surely discovered in the former and might not be in the latter. Sloughing or necrosis of the uterus was an accident of the radical operation which never occurred in a simple hysterectomy. In a series of 500 cases of Wertheim's there was sloughing of the ureters in thirty cases; in five it occurred in both ureters. The most frequent result of this accident was a ureterovaginal fistula. The cause of the necrosis of the ureter in most cases was the interference with the blood supply during the operation. Injuries to the bladder more frequently followed the radical than the simple hysterectomy. Paralysis of the bladder requiring catheterization was of frequent occurrence after the radical operation. Kidney infection frequently followed bladder infection, and infection was favored by the condition of the ureters. To the same extent that the lesions of the bladder and ureter were more frequent in the extended operation, the renal complications would be more common. Bleeding most frequently occurred from the radical operation and might be exceedingly difficult to control. The ligation of the anterior trunk of the internal iliac arteries would diminish the amount of the hemorrhage. It was probable that the risk of infection was no greater in the radical than in the simple hysterectomy for a carcinoma of the cervix uteri of the same extent. As to the results, statistical and theoretical evidence favored the radical operation. From the European clinics larger series of cases were reported showing a much higher percentage of permanent cures than had been obtained by any other operation. The more extensive an operation was for a malignant growth, the greater were the chances of a permanent cure if the patient survived the operation. This was true of cancer in the uterus as in other organs. In conclusion Dr. Taylor said that his treatment of carcinoma of the cervix uteri was as follows: (1) For the favorable cases, a patient in a good general condition, an abdominal wall without an excess of fat, no associated pelvic lesion to increase the operative risk, and a limited growth, he advised the radical operation. (2) For a limited growth in a patient who was a bad risk on account of general or local condi-

tions, he advised usually a simple abdominal hysterectomy, occasionally a vaginal hysterectomy. (3) For the so-called inoperable case, he advised radium, x-rays, and the cautery. In this class because of the favorable reports that were published following the use of radium, x-rays, and the cautery, he included cases that formerly he submitted to operation. If after the use of radium, x-rays, or the cautery the case became operable he removed the uterus.

Dr. GEORGE H. MALLET said that one of the strong points in favor of the Percy operation was its low primary mortality; but since life insurance companies figured an average of 2 per cent. mortality for all abdominal operations, it was not surprising that a death would sometimes follow this procedure in the most skillful hands. Thirty years ago heat was the only operative means used in the treatment of carcinoma of the cervix. In 1892 Byrne reported eighty-one cases where the whole cervix was involved, and upon whom he had operated upon with heat. There was no mortality. Of these thirty-one were lost sight of, eighteen lived over five years. Considering all of the thirteen lost to have died in less than five years after the operation, he would still have 20 per cent. of cures. In 1897 Dr. Mallett assisted Dr. Byrne in operating upon a patient; he used his battery and instruments as described by Dr. Holden. The operation required about two hours for its performance. Thirteen years later this patient was still living. Percy had placed the operation upon a more scientific basis; opening the abdomen was of distinct advantage because it permitted the operator to control the heat when applied to the uterus. Ligation of the blood vessels of the pelvic organs was also an important feature. In many of Dr. Mallett's cases, in addition to the heat, radium was used but not as a routine measure. It would be a wonderful thing, and he hoped that it would be proved to be true, as claimed by Percy, that the heated iron would kill the cancer cells within a radius of from one and a half to two inches. Balfour of Mayo's Clinic had stated that of sixteen cases where the heat had been used and the uterus removed one month later, in thirteen there were found no live cancer cells.

Dr. JAMES A. CORSCADEN said that the treatment of these cases should be excision of the uterus, which not only hoped to get the gross mass out but the microscopical cells as well. When the tumor reached the stage where it could not be so excised then any method which would improve the patient is justifiable. There were two factors to be considered, namely, the local and the general effect upon the growth; whether the heat applied should be of high degree or of low degree, and whether the heat in the instrument would reach further in one method than in the other, this was a matter of exact observation. What had been shown tonight was beautiful in that both pathological processes were presented, first, the greater susceptibility of muscle and second, the greater susceptibility of carcinoma. Another factor that had not been talked upon enough was general immunity; this was one factor that had been proven by direct experiments upon animals, experimental cancer in rats. Murphy had shown what a great factor the lymphocyte was in immunity. Another factor was the fact that whatever serum therapy was used, synthetic chemical, or serum, there was always a high body temperature. Just what produced it as yet they could not tell. The equanimity with which some older surgeons viewed certain infections in carcinoma, and especially after operations upon the breast, might be recalled. Some stated that they had rather have an infected wound than one that was clean. He referred to Coley's work with the streptococci of erysipelas. Percy's treatment he believed was certainly indicated in these cases, but he was not ready as yet to say that this treatment afforded better results than did radium. It produced a leucocytosis and raised the body temperature. There was not only a local leucocytosis, but a general leucocytosis. The polymorphonuclears and the number of lymphocytes were greatly raised at the same time. Radiotherapy was often of great value in these cases.

Dr. BROOKS H. WELLS said that the tendency during the past decade had been to restrict the indications for the radical operation. He felt that if the disease was met with in the early stages, and if they felt sure they could remove it by a radical operation, the radical operation should be done and they would get good results. But, on the other hand, if the disease had progressed to a point where it was certain they could remove but a portion of the diseased area, even though it be a con-

siderable portion, the question then would arise whether the radical operation should be attempted at all. Percy's operation followed by either the x-ray or radium often gave excellent results. They must all realize the importance of immunity and this carried much weight in making up the prognosis. However, the most important factor in these instances was the early diagnosis and today it was made earlier than it was fifteen years ago. If the scrapings were more carefully examined they would find many cases of carcinoma that otherwise would be overlooked.

Dr. HERMANN J. BOLDT said that only last week he operated upon a patient who had been sent to him only two weeks ago by a surgeon well known to them all, who said the patient would be entirely well in one week. This patient subsequently saw Dr. Brettauer, who told her that he was in no position to make a diagnosis until an excision had been made and a piece of the tissue submitted for examination. Two days afterward she came to see Dr. Boldt, and he told her the same as did Dr. Brettauer. Neither of them knew that the other had seen this patient. She finally consented to have a piece removed for diagnostic purposes. She had a well marked adenocarcinoma. He did not make a careful recto-vagino-abdominal examination until attempting a radical operation. He then found that the patient was practically inoperable. But, bearing in mind the fact that one did not know when carcinoma was fit for a total ablation or a radical operation or not, he opened the abdomen and did some extensive intra-abdominal work and verified what Dr. Brettauer and he had believed existed. The diagnosis might have been made earlier. Apropos of the radical operation, he thought that Dr. Taylor had struck the keynote in what he had said regarding simple hysterectomy and radical operation. Nineteen out of twenty cases done now and called radical operation were nothing more than simple hysterectomies. To do this work thoroughly was not a simple matter at all; it was a difficult operation. They had not yet had sufficient experience with it. Dr. Boldt went even further than Dr. Mallett, who said the first ten cases should not be counted against the man; twenty-five cases should not be counted against him. It was a dangerous and difficult piece of work. Laying bare the ureters was not so difficult, but in freeing them to the bladder, the difficulty commenced. Free venous bleeding occurred occasionally. Dr. Taylor was correct in saying that there was one class of cases in which the vaginal operation was to be preferred, cases with extreme obesity. If he had to deal with a very obese woman he did not care to try the abdominal route. The methods to be employed in these cases should be studied further and they must have more experience in order to enable them to do the operation properly. In regard to the destruction of the carcinomatous tissue by the cautery, Dr. Mallett had stated that, if one could destroy the cells from one or two inches from the site of the application of the cautery, the results would be excellent, but he placed in the word "if." Whether they used the high degree of heat or the low degree, the carcinomatous cells were destroyed but a short distance from the cautery. Tying the blood vessels was a method which the late Dr. Pryor advocated for the relief of the bleeding, lessening the discharge, and making the patient more comfortable. The cautery operation he believed to be the best, one of the most valuable therapeutic agents that they possessed for the palliative treatment. So far as radium was concerned he did not hesitate to say, judging from reports, that it was of the utmost value. Unquestionably much more could be achieved with the use of radium than many believed. Many patients who were considered inoperable became operable by the use of this agent, as reported by men of unquestionable veracity.

Dr. WILLIAM S. STONE said that he had had the opportunity of observing some of Dr. Mallett's work with the Percy operation. In one case, which he had examined several months after the operation had been performed, there were no gross evidences of carcinoma in the pelvis. He had also seen Dr. Percy himself perform two operations, in both of which, through the courtesy of Dr. Mallett, he had the opportunity of making an examination immediately before and after the operation, and that he was much impressed with the immediate result of the procedure. In one case, for example, in which the left broad ligament was extensively involved, rendering the uterus immovable, this thickening and hardening at the completion of the operation almost completely disappeared, and the uterus moved more freely. The truth was that it was a desiccating

process, taking the water away from the tissues. The examination of these patients immediately after operation might lead one to think they were then suitable for the radical operation. But he was also impressed with the fact that the operation was not a minor affair. As with the radical operation one should hesitate very much before attempting it, unless he had a comprehensive knowledge of the extent of the disease and all the conditions which make it applicable. To be safe and efficient, it required an operator who was well acquainted with the disease and the technique. Dr. Stone expressed his enthusiasm for the possibilities of the use of radium, especially in cases of carcinoma of the corpus uteri, but thought that the so-called Percy operation offered an additional therapeutic resource in certain advanced cases, in which neither the radical operation nor radium could be applied.

Dr. EMILY DUNNING BARRINGER said that the use of the cystoscope was very valuable in helping to clear up some of the borderland problems. In certain cases of uterine carcinoma the growth progressed forward into the bladder region out of all proportion to the parametrical involvement. Should these cases have a preliminary cystoscopy they would probably be considered inoperable and thus become a factor in reducing postoperative mortality. The bleeding that occurred from the bladder interested her very much. She questioned whether this might not be due to a rupture of a varicose vein in the bladder wall. In certain cases even if there be no definite carcinoma of the bladder there might be very large varicose veins in the bladder mucosa due to pressure of the adherent carcinoma. The manipulation necessary in removing the growth might have stirred up such a varicosity and started the hemorrhage. Owing to possible pressure of the growth on the ureters in cases of uterine carcinoma, she suggested that a preliminary phenosulphonephthalein test might be of value in estimating a possible case of postoperative renal insufficiency. She asked Dr. Taylor if any of his postoperative mortality was due to this cause.

Dr. Taylor closed the discussion. In answer to Dr. Barringer's inquiry he said he could not recall an instance among his cases in which death was caused by renal insufficiency. He thought that her suggestion regarding rupture of varicosities in the bladder causing the hemorrhage in the case she reported was probably correct; at least it was a reasonable one. With regard to the mortality following the Percy operation, a case that Percy himself did at the Woman's Hospital some two or three years ago died. Percy acknowledged that there was a definite mortality accompanying his operation. It might be better to give the credit of this operation to Byrne; the part added by Percy was that of opening the abdomen enabling one to do more thorough work. The late Dr. Pryor was the first to suggest the ligation of the blood vessels and to do it. In regard to the treatment of carcinoma of the cervix in general, an operation was practically the only means of cure. The mortality of the operation should not be considered too much. If in one series of cases there was a 10 per cent. risk and a 10 per cent. cure, and in another series of cases treated by a different method there was a 40 per cent. risk and a 40 per cent. cure, any of them would prefer the 40 per cent. risk with its 40 per cent. cure.

SECTION ON MEDICINE.

Stated Meeting, Held January 18, 1916.

DR. NELLIS B. FOSTER IN THE CHAIR.

Theories of the Etiology of Pernicious Anemia.—Dr. KARL M. VOGEL read this paper in which he said that the etiology of pernicious anemia belonged to that pleasant group of subjects which were always agreeable to discuss because their ignorance concerning them was so extensive that it was very easy to have a great deal to say about them. There was a tendency to adopt certain changes in the conception of the different types of anemias owing to the somewhat clearer insight they were gaining into their nature, and a comprehension of this altered point of view was necessary in order to understand the relation which pernicious anemia was now believed to bear to the other forms. That view of anemias which made the distinction between primary and secondary anemias must be abandoned, for, logically considered, there could be no such thing as a primary anemia, since the blood in itself was not an organ, but was the direct product of the activity of the various

hematopoietic organs or systems, and in a sense might more properly be regarded as a secretion than as an organ. It must be conceded that strictly speaking all anemias were secondary. The anemic state in the last analysis was the result of a disturbance of the normal equilibrium between blood destruction and blood production and it was found that in one group of anemias it was chiefly the former process which predominated, while in another it was a deficiency of the latter. Therefore the wholly reasonable attitude was to divide the anemias into two broad classes, one of which embraced those types in which the most conspicuous element was a reduction in the production of blood elements, while in the other group the significant feature was their abnormal destruction. To the former belonged the anemias due to cachexia, wasting diseases, tumors, some of the toxic anemias, aplastic anemia, and osteosclerotic anemia. In the other group came the anemias due to loss of blood through hemorrhage, either acute or chronic, and the entire class of hemolytic anemias, such as those caused by hemolytic poisons of definite nature, like pyrocin, phenylhydrazin, nitrobenzol, toluylenediamine, potassium chlorate, etc., and those of a more vague character, like the toxins of certain intestinal parasites, malarial organisms, or those sometimes produced in pregnancy, syphilis, and carcinoma. Then there were the various types of hemolytic icterus, and finally the progressive pernicious or Biermer's anemia. Chlorosis being a disease *sui generis*, depending most probably on a constitutional anomaly of the internal secretions of the female sexual glands, and differing in fundamental characteristics from the other forms of anemia could hardly be linked with any of them. After reviewing the observations of various investigators with reference to the etiology and pathogenesis of pernicious anemia, Dr. Vogel summed up by saying that pernicious anemia was a symptom complex based fundamentally on a condition of increased hemolysis plus a toxic action on the bone marrow, but the origin of these manifestations was highly involved and depended upon a variety of partial causes which were differently associated in different cases. One of these factors seemed to be an abnormality of splenic function, conveniently termed hypersplenism, while another was the presence of some hemolytic agent. In occasional instances which they had learned to recognize this agent was a toxin produced by the fish tape worm, or by pregnancy, or by syphilis. In the majority of cases, however, it was still quite unknown, though it was probably of endogenous nature, and there was much evidence in favor of the view that it belonged to the rather indeterminate group of ether-soluble substances termed lipoids. Possibly this lipoid substance served only to render some other agent actively hemolytic, or perhaps some action occurred such as had been shown in experimental toluylenediamine anemia. Here the hemolysis was not caused directly by the chemical itself, but by a newly formed lipoid produced in the liver as the result of the poisoning. In addition there was probably a disturbance of the lipoid metabolism of the body in general, resulting in a decrease of the antihemolytic properties of the serum. This might reasonably be associated in their speculations with a disturbance of the functions of the ductless glands, notably the adrenals, for studies on the cholesterol content of the adrenal cortex and the blood had shown that an intimate relation existed between the two, while the antihemolytic properties of cholesterol had been well established. Still, though cholesterol protected animals against experimental cobra venom anemia, attempts to use this agent in the treatment of pernicious anemia had been quite fruitless. Furthermore, one was led to believe that there must be some constitutional anomaly, some inherent weakness, either temporary or permanent, which rendered the body susceptible and permitted the other agencies to take effect. No one of these could itself be termed the cause of the disease, for neither the Bothriocephalus, pregnancy, or syphilis, oral sepsis, gastric achylia, nor hypersplenism alone could produce it, and all such entities formed only single links of the etiological chain. In speaking of the treatment the author said that the effects of splenectomy and transfusion, either separately or combined, were encouraging, and that these two measures gave the most hopeful outlook in treatment. From the seven or eight splenectomies that had been performed at St. Luke's Hospital by Dr. Downes they had gained the impression that the subsequent effects of transfusion were more marked and persisted longer than in cases in which the operation had not been done. Greater

care seemed necessary in the choice of donors for transfusion. There were surely more subtle factors at work than had been detected by the relatively coarse tests for hemolysis and agglutination now available, which were perhaps concerned with the colloids of the blood, as suggested by Doerr and Moldovan in connection with anaphylaxis and coagulation phenomena. It was always advisable, if a transfusion was not attended by good results, to select a different donor for the next repetition of the measure. The benefits of the procedure depended more on the stimulation that it gave to the bone marrow than on the mere pouring into the vessels of a large volume of blood, and small transfusions of one to two hundred c.c. frequently repeated were more likely to benefit the patient than massive transfusions given as a last resort when the patient was in *extremis*. In gauging the effects of transfusion and of therapeutic effects in general they had found in their cases that watching the fluctuation of the reticulated cells as brought out by supravital staining was of much interest and definite practical value in measuring the degree of bone marrow reaction. Another very useful guide to the intensity of the hemolytic process and the effects of such measures as splenectomy or transfusion was furnished by a study of the urobilin in the urine and particularly in the stools. In addition to confessing that their efforts to cure the disease were still unavailing, they were obliged to admit that it was distinctly increasing in frequency. This had been noted not only in Europe but also in this country. At St. Luke's Hospital, during the seventeen years from January 1, 1899, to January 1, 1916, they had had 117 cases of pernicious anemia. Of this number twenty-two were admitted during the first five-year period; thirty-two during the second five-year period, and forty during the third period of five years, while during the last two years there had been twenty-four cases, which was at the rate of sixty cases for the coming five-year period.

A Study of von Jaksch's Anemia.—Dr. RALPH G. STILLMAN presented this communication, based upon studies in the pathological department of the New York Hospital. He said that although cases of anemia accompanied by enlargement of the spleen and occurring in children were described clinically by Gretscl as long ago as 1866, and pathologically by Cohnheim in the preceding year, it was not until more than twenty years later, when the examination of the blood began to play a prominent part in clinical investigations, that the various conditions included under this head began to be separated one from the other. In 1889 von Jaksch described a case of leucemia in a child of fourteen months, and in the following year he reported three cases of enlarged spleen in children, a condition which he called anemia pseudoleucemica infantum. This was characterized by a diminution in the hemoglobin and in the number of red cells, marked persistent leucocytosis, sometimes glandular enlargement, slight enlargement of the liver, a marked enlargement of the spleen, which was out of all proportion to the size of the liver, and a tendency to recovery. One patient died and the autopsy revealed no evidences of syphilis or leucemia. After this publication cases were recognized with comparative frequency and there were numerous reports in the literature which dealt with the subject. However, in spite of the comparatively abundant material and the obviously large amount of time which had been devoted to it, they had advanced but a very little way toward a clear understanding of the conditions. Part of this was due, no doubt, to the lack of autopsy material but the greater part was due to the fact that their investigations led them to a blank wall beyond which their present knowledge and methods did not permit them to penetrate. In the study of this condition he said he had nothing very new or startling to present, but would endeavor to clarify one or two points which had been the source of much discussion and record the results of a method of treatment which, though not new, had not as yet been very extensively followed. Three cases of von Jaksch's anemia had recently been under observation in the New York Hospital and formed the basis for the present discussion. Von Jaksch's anemia might be defined as a condition occurring in children and marked by anemia, slight enlargement of the liver, marked enlargement of the spleen, and sometimes an enlargement of the superficial lymph nodes. The blood picture was characterized by a great diminution in the red cells and the hemoglobin, and a persistent leucocytosis. Most of the patients showed a definite tendency to recover. The abnormal blood pic-

ture in those who lived might persist for a very long period of time. Von Jaksch's anemia was frequently associated with rickets. In some instances syphilis had been accepted as a causative factor while tuberculosis, gastrointestinal upsets, and infections might at all times play a part. It was logical to conclude that von Jaksch's anemia was due to the action of toxic or infectious agents which might or might not at the same time produce rickets. The source of these toxins was not necessarily in the gastrointestinal tract. The picture in the spleen was connective tissue increase, atrophy of the Malpighian bodies, and myeloid metaplasia. The symptoms of von Jaksch's anemia consisted chiefly of the symptoms of anemia in general, pallor, edema, weakness, dyspnea, etc., a large liver, and a very large spleen, with a characteristic blood picture. The onset was gradual and the patient usually came under observation with a well marked enlargement of the spleen. The symptoms which were due to the anemia itself might be masked by the presence of symptoms due to the accompanying conditions such as syphilis, tuberculosis, or rickets. The blood picture must be depended upon for a diagnosis. Many of these cases did eventually recover. The treatment had been unsatisfactory in the majority of the cases. Since, however, they frequently showed a tendency to recover, almost any treatment might be followed by improvement.

The Broader Aspects of Hematological Diagnosis.—Dr. E. E. BUTTERFIELD spoke quite at length on the pathogenesis of the blood picture in the anemias and of the morphology of the leucocytes. He said it was possible by chemical and physical examination of the blood and blood serum to learn many things. Together these two methods of examination had shown many things and had proved useful in nephritis and diabetes, and by them it was possible to distinguish between edemas of cardiac and those of uremic origin, so that it was not expecting too much to hope that they would enable them to learn more of the different types of hematological disease.

Dr. JAMES EWING said that anyone interested in blood diseases must have had his enthusiasm aroused by the able discussion which they had heard this evening. Although he had been out of blood work for several years it had renewed his old interest. In Dr. Vogel's paper he had been particularly interested in the views expressed as to the relation of hemolysis to pernicious anemia. One recognized that Dr. Vogel believed that pernicious anemia was essentially a hemolytic process and that one must make search for some hemolytic agent to account for it, but it was not enough in seeking the pathogenesis of pernicious anemia to stop here; one must take account also of defective hematogenesis. Loss of blood alone did not account for pernicious anemia. It was recorded that a tuberculous patient in the course of two years had lost an amount of blood equivalent to five times the normal blood volume and still pernicious anemia was not established, while, on the other hand, cases of hemorrhoids with slight bleeding might develop pernicious anemia. The progressive character of pernicious anemia was dependent on the condition of the bone marrow. One must have something to start up the anemia, but it did not progress unless there was a defective hematogenesis. In the discussion of the therapeutics of blood transfusion Dr. Vogel seemed to have recognized this for he spoke of the advantages of the repeated injection of small amounts of blood as being more effective in combating pernicious anemia than single large doses. This was because the small doses stimulated the hematogenetic function of the bone marrow, thus enabling it to combat the hemolytic agent. The factor of congenital predisposition might be emphasized. Only certain individuals were susceptible to the disease. The production of the exact prototype of the disease in animals had not been effected experimentally, because they were not susceptible to the progressive disease. So one could conclude that in human subjects, many of whom were exposed to hemolytic toxins while few developed pernicious anemia, there must be an underlying congenital predisposition, which was an essential factor in the etiology of pernicious anemia. Dr. Vogel should be congratulated for having put emphasis on the etiology of blood diseases, rather than on the morphology of the blood. Some years ago physicians spent all their time developing stains and methods of making the blood count. Happily that era was past and the emphasis was now being placed on the etiological factors and the pathogenesis, and an attempt to get at an

effective therapy based on the fundamental facts of the disease.

With reference to Dr. Stillman's paper on von Jaksch's anemia, very little was known of this condition until within recent years, but clinical and pathological studies indicated that it did not have an etiology different from that of pernicious anemia in the adult, but that the same factors that produced pernicious anemia in the adult produced von Jaksch's anemia in the child. Dr. Ewing said he doubted if pernicious anemia ever occurred in children. He had once made a diagnosis of congenital pernicious anemia in an infant, but he regarded it as diagnostic gymnastics. Anemia in infancy had certain characteristics which differentiated it from pernicious anemia of adults. It had a good prognosis, a tendency to leucocytosis, and a notable activity of the red cells of the bone marrow. Most of the children got well. The relation of rickets to von Jaksch's anemia was of interest. In rickets there was an extreme hyperemia of the bone marrow and interference with blood formation, favoring exodus of the marrow cells into the blood. With some there had been a misunderstanding of the function of the spleen. They found disintegrated red blood corpuscles in the macrophages of the spleen and concluded that it was a dangerous organ and should be removed, whereas it was removing alienated cells from the blood, thus performing a useful function to the organism.

Dr. Butterfield had spoken chiefly of the pathogenesis of the blood picture and it was to be hoped that he would put his remarks into writing so that they would be available. He felt that Dr. Butterfield's attitude was the result of too strong a diet of hematological literature, and that he had been reading a great deal with reference to the morphology of leucocytes and he sympathized with the feeling Dr. Butterfield had expressed when he said that the morphological phase of the subject had been very much overworked. In lymphatic leucemia there was purely an excess of lymphocytes in the nodes and these had nothing to do with the reticulum cells of the lymph follicles. With reference to the transition between red and white cells, these were two separate classes of cells developed very early in embryonal life, the white cells arising from one end of the embryo and the red cells from the other end, and there was little support for the opinion that there was any transition between them. Dr. Ewing said that what he had written years ago in support of the view that there were such transitions he would now retract. The question had been brought up as to whether any of these cell changes were reversions to the embryonal type. It would be better to regard them as degenerative changes. Leucemia, like leucocytosis, must be regarded as a symptom and not as a definite disease. It arose in a great number of conditions and when it had gained a certain momentum it became chronic. It was quite possible that there were five or six pathological conditions in which a leucemic blood picture was present. It was better to pick out the etiological factors and direct attention to them, since leucemia was a symptom and not a disease.

Morphinism a Curable, Physical Disease.—Ernest S. Bishop states that in morphinism *per se* we have one of the most definite and curable diseases in medicine. The desire for morphine in the majority of cases is simply the expression of bodily need, and the fundamental condition is the changed physiology which makes morphine a necessity for organic satisfaction and adequate carrying on of organic function. It is complicated by and complicates other diseases exactly as do other morbid bodily processes; and every case is absolutely individual. Treatment which is based upon the recognition and removal of fundamental conditions as they appear in the individual case will give surprising results. Sufficient understanding of the disease mechanism and its symptomatology, and the ability to estimate accurately the patient's bodily need, the maintaining of him in functional and metabolic addiction-drug balance, and the securing of good tone and nutrition before withdrawal, are of far more importance than any method of morphine withdrawal. With study and education, and this applies to members of the medical profession as well as to the laity, will come a rearrangement of our present attitude toward morphine addiction and the treatment of its victims, and in its place will stand as a part of the ethical, rational practice of medicine, the treatment of a new disease.—*American Medicine*.

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

CHANGES IN THE FOOD SUPPLY AND THEIR RELATION TO NUTRITION. By LAFAYETTE B. MENDEL. Published by the Yale University Press, contains 61 pages. Price, 50 cents.

MEDICAL ALUMNI CATALOGUE. Published by the Alumni Association, contains 97 pages.

BULLETIN OF THE ST. LOUIS UNIVERSITY. Published by the University, with 41 pages.

PROCEEDINGS OF THE MEDICAL ASSOCIATION OF THE ISTHMIAN CANAL ZONE. Published by the Panama Canal Press. For the half-year—April, 1914-October, 1914. 163 pages, with illustrations.

CHIMIE PATHOLOGIQUE TROPICALE DE LA RÉGION ATLANTIQUE. By Dr. G. DELGADO PALACIOS. Published by Lit. y Tip. del Comercio, Caracas; 318 pages, with illustrations.

THE NEW PUBLIC HEALTH. By HIBBERT WINSLOW HILL. Published by The Macmillan Company; 206 pages. Price, \$1.25.

TRANSACTIONS OF THE AMERICAN SURGICAL ASS'N. Published by William J. Doran, Philadelphia; 825 pages; with illustrations.

A SIMPLE METHOD OF SHORTENING THE ROUND LIGAMENTS OF THE UTERUS FOR THE CURE OF RETROVERSION.

BY J. H. KELLOGG, M.D.

READING, OHIO.

SINCE Alexander of Liverpool devised a method of shortening the round ligaments for the cure of retroversion of the uterus, more than a score of methods have been proposed for the relief of this most frequent of the visceral displacements peculiar to women. There are few, if any, pelvic lesions for the relief of which so many and so varied surgical procedures have been proposed, and this fact clearly evidences the general recognition of the need of surgical intervention in this condition. The multiplicity of methods brought forward also indicates that none of them have proven altogether satisfactory.

The method which will be described in this article has been in use by the writer for more than twenty-seven years. The first cases were operated upon in the autumn of the year 1888. The method has now been employed by me in more than 1,600 cases, and by other surgeons who have made themselves familiar with the technique of the operation in several hundred more cases.

The essential features of the method were described several years ago in papers read before medical bodies, and published in medical journals and in the *Transactions* of the Michigan State Medical Society; but as some important modifications have been made in recent years, the writer has thought best to comply with the request of a number of physicians who have seen the operation, to prepare this paper in which a more exact and detailed account of the operation will be given.

There appeared some time ago in an English periodical a description of my operation under the name of "The Blunt Hook Method," written by a surgeon who had twice visited the writer's clinic for the purpose of learning the technique of the operation, but without mention of the author's work. The presentation of this paper is also desirable by reason of the fact that the descriptions of the technique of the method which have appeared in text-books and papers by various medical writers have not been such as to give an adequate idea of the several steps essential to the success of the operation.

Preparation of the Patient.—The operation may be performed in a suitable case at any time except during menstruation and a few days before or after. The bowels should be not only well emptied, but should be well regulated so as to move easily two or three times a day. This may be accomplished in cases in which no serious mechanical

obstruction exists, by careful control of the diet and the free use of paraffin oil, agar-agar, and bran. This point is of much importance, as straining at stool is especially perilous while the ligaments are softened by the healing process during the first weeks following the operation. Overlying of the uterus by a distended pelvic colon and violent straining at stool are frequent causes of retroversion, and may easily become a cause of relapse. The vagina should be free from infection. Examination should be made to insure freedom from inflammatory disease of the ovaries and tubes and adhesions of the uterus or appendages to the pelvic walls or contiguous viscera.

Adhesions between the left tube and ovary, and the pelvic colon or its mesentery are so frequent that there is a distinct advantage in giving the patient an *x-ray* examination by means of the bismuth meal combined with injection of the colon with bismuth paste. The writer recalls one case of failure in which the cause was an adhesion between the pelvic colon and the uterus, a condition undiscoverable in the very fleshy patient when the colon was empty, as the pelvic loop moved easily with the uterus. When the pelvic colon was filled, however, its weight pulled the uterus backward, and after the operation the continued tension gradually stretched the ligaments and forced the fundus backward. An *x-ray* examination would have revealed the true state of things.

An *x-ray* examination of the alimentary canal, including visualized palpation by the aid of the fluoroscopic screen, may also give highly important information concerning possible adhesions of the pelvic colon or of the terminal ileum, incompetency of the ileocecal valve, gallstones, and other conditions which can be remedied only by surgical intervention.

The preparation of the skin should be as for laparotomy. The pubic hair is removed and the skin well scrubbed the night before, then an application of 2 per cent. iodine solution is made and sterile dressings are left on over night. In the morning a second application of iodine is made and is washed off with alcohol just before the operation.

The Anesthetic.—The writer has for many years employed nitrous oxide and oxygen almost exclusively. In forty or fifty cases the operation has been done with local anesthesia.

Special Instruments Needed.—The special instruments required are two blunt hooks, two retractors, and an aneurysm needle. The blunt hooks are very similar to those used by ophthalmic surgeons in operations for strabismus, but are larger and stronger. The retractors likewise are similar to those used in retracting the eyelids. An ordinary aneurysm needle may be employed, but one specially modified is desirable. (Fig. 1.)

The Operation.—Almost without exception a curettage is required when the uterus has been long retroverted, as a pathological condition of the endometrium is almost invariably present. The curette rarely fails to bring away a considerable quantity of vegetations. These should be always examined for the reason that occasionally evidences of early malignant degeneration are found. If a serious laceration of the cervix exists, it is repaired. A large, heavy cervix which has become a mass of cicatricial tissue should be amputated.

When the pelvic floor is greatly weakened, resulting in rectocele or cystocele, these conditions must be corrected by a plastic operation.

Before or after the curettage the uterus is carefully replaced by bimanual manipulation. Great care must be taken to see that both the uterus and the appendages are brought well forward. When released, the uterus should remain in position. If it falls backward at once, or quickly settles down into a retroverted position, adhesions are probably present. The uterus may not be adherent and yet one or both ovaries or tubes may be attached to the pelvic wall or to a movable viscus, as to the pelvic colon or to a loop of the small intestine. Adhesions to the intestine are not always easily discoverable by the palpating finger, except in cases in which the abdominal walls are very thin. Here an x-ray examination may render special service, especially if the roentgenologist is possessed of a high degree of skill in visualized palpation.

When marked ante flexion or retro flexion exists a stem pessary is introduced. A carefully fitted lever pessary is placed to support the fundus, and to prevent all straining upon the ligaments. The pessaries are usually retained for two or three months while the intestines are becoming readjusted and the abdominal walls strengthened. When the patient leaves the hospital, she should be informed of the presence of the pessaries and told to place herself at once under the care of a competent physician, who will attend to their removal at the proper time.

The greatest care must be taken in the technique of this operation to avoid infection of the wound. If bacteria gain access to the wound, suppuration is likely to occur, on account of the unavoidable traumatism to which the ligament is subjected and the interference with the blood circulation in the ligament due to stripping off its peritoneal coverings and its anchorage by weaving into the aponeurosis of the external oblique.

The Incision (Fig. 2).—A separate incision is required for each ligament. Care is taken to make the incisions symmetrical; they generally lie wholly within the area covered by the pubic hair. The length of the incision need not be over three centimeters, and in a thin subject an incision two centimeters in length is often sufficient. It is important that the incision should be made at the right point. Find the middle of Poupart's ligament, place the finger upon this point, then start the incision at a point about one centimeter nearer to the pubic spine and two centimeters internal to the ligament of Poupart. The incision should extend only through the skin proper and should not include the subcutaneous fat. This is necessary to avoid cutting the rather large superficial epigastric vein which runs directly across the line of incision. If the vein is injured, the danger of infection will be increased owing to stasis of fluids in the region of the wound. If the incision is extended too far

downward a branch of the superficial epigastric artery will be encountered. If care is taken to avoid these vessels, ligatures will not be required.

Blunt Hook Dissection (Fig. 3).—After the skin has been incised, the knife is laid aside; the remaining dissection is made entirely with the blunt hooks. The two points of the hooks are placed together in the center of the wound, pressed into the tissues, and separated by drawing toward the angles of the wound. By lifting the angles of the wound with the hooks, the wound is made to gape and the retractors are then introduced, first one, then the other; this procedure is repeated as many times as may be necessary to reach the aponeurosis of the external oblique. When the aponeurosis first comes into sight, it is seen shining through a thin, nearly transparent, deep layer of the superficial fascia, which is closely attached to Poupart's ligament. This fascia must be divided and drawn aside by the retractors in order to bring Poupart's ligament plainly into view.

By means of the retractors the loose skin may be pulled about in various directions. Generally, Poupart's ligament will be very clearly seen when the last thin fascial layer is drawn aside. If necessary the gloved finger may be introduced into the wound to verify the ocular observation. The finger should be passed down along Poupart's ligament to locate the external ring and the spine of the pubes.

Picking up the Ligament (Figs. 4 and 5).—Now fix a point along the ligament about one-third the distance from the pubic spine to the anterior superior spine of the ilium. One centimeter internal to this point, make a puncture through the roof of the inguinal canal with the blunt hook held in the left hand and split the tendinous fibers of the aponeurosis for about one-half centimeter and introduce the other hook with the point turned outward toward Poupart's ligament. The round ligament normally lies in the groove which runs along Poupart's ligament. Dip the hook close beneath Poupart's ligament, and carefully pull up whatever the hook engages. If the ligament does not appear, the hook is introduced again and made to explore the tissues one or two centimeters in each direction along Poupart's ligament. If the ligament is not discovered, turn the hook inward and endeavor to find it beneath the outer border of the internal oblique, where it is sometimes found.

How to Recognize the Round Ligament.—This may be recognized by several characteristics. (1) It is a distinct structure. (2) It differs in color from other structures, looks white like a tendon, although not quite so smooth and glistening as a tendon. (3) Over the surface of the ligament small tortuous veins may be seen which disappear when traction is made upon the ligament and fill when the tension is relaxed. It should be noted that these veins are sometimes greatly enlarged and varicose. (4) The ligament is pulled out more easily than other structures. When, however, the nerve which comes with the ligament is caught with it by the hook, the ligament is held back somewhat, but by separating or cutting the nerve the ligament may be very easily drawn up and does not snap back into the canal, as do other tissues when released.

Care must be taken to avoid dragging out the properitoneal fat or picking up the branches of the deep epigastric artery or vein. If the hook is pushed too deep it will penetrate the floor of the inguinal canal; as a result, the properitoneal fat will be pulled out, together with a branch of the

deep epigastric vein, which may be easily torn, and cause a smart hemorrhage, and possibly a hematoma in the ligament. When it happens that the deep vessels are pulled out they should be released at once, or, if injured, caught with forceps and tied immediately.

FIG. 1.—Author's blunt hook and retractors for use in round ligament operation.

Not infrequently the first tissue brought up will prove on examination to be the edge of the internal oblique muscle. When under tension the muscle or fascia may very much resemble the ligament. The muscle differs in the fact that when pulled it resists, tears easily, and does not show the distinct and characteristic structure of the ligament.

Failure to find the ligament may be due to several causes.

1. The ligament may be drawn down under the

FIG. 2.—Skin incision.

internal oblique to an unusual degree by long continuous and excessive strain.

2. In very stout persons, the ligament may be buried in fat in the lower part of the canal.

3. The ligament is sometimes obscured by a mass of veins, due to a condition analogous to varicocele in men.

4. A more common cause of failure is incorrect placing of the incision or of the puncture through the roof of the inguinal canal. The ligament must

FIG. 3.—Blunt hook dissection.

be sought in exactly the right spot as above described. If the hook is introduced even one centimeter away from the proper point, the ligament will be found only with much difficulty. The ligament is most easily secured at a point about one centimeter below the internal ring, and of course will not be found above the internal ring. If the ligament is sought too far inward, only muscle will be found. By persevering effort the ligament may sometimes be found when the incision is not rightly placed, but only after the internal oblique muscle has been much lacerated, which should be avoided, as it delays healing of the wound and is likely to be a cause of discomfort to the patient later.

FIG. 4.—Passing blunt hook.

The ligament should always be sought at the outer border of the internal oblique and should be drawn out from under the muscle instead of being pulled up through it. It is, of course, useless to seek for

the ligament below Poupart's ligament, although some operators have been sufficiently careless in their dissection to make this error. A New York surgeon who visited me some years ago to witness this operation, and who afterward did the operation

strong ligament, fully half a centimeter in diameter.

One ligament may be small and the other large; the left ligament is most often the larger. This is, perhaps, due to the fact pointed out by the writer some years ago that the left leg is somewhat better

FIG. 5.—Picking up ligament.

in several cases, mentioned in a paper that he had on three different occasions drawn up the femoral vein. If care is taken to keep above Poupart's ligament this mistake cannot occur.

5. The ligament is sometimes so slender that its recognition is very difficult. Small ligaments are most likely to be found in poorly developed women who have not borne children and in whom the uterus is retroverted to an extreme degree. I have many times found a ligament the distal part of which was not as large as an ordinary knitting needle, but even in these cases the ligament by very gentle traction may be pulled up, and the proximal portion is found to broaden out rapidly, so that substantial structures for anchorage may be secured.

FIG. 6.—Unusually large ligament.

6. The ligament is sometimes so unusually large that it is not readily caught by the hook and one is sometimes surprised after several minutes of fruitless search by the sudden appearance of a large,

FIG. 7.—Stripping off peritoneum.

developed than the right leg in right-handed persons.

7. The ligament is sometimes invested by fascia and fat and not so easily recognizable as in normal cases. In such patients it is necessary to tease the ligament out from the other structures with which it is closely incorporated.

8. Anomalous conditions of the ligament are sometimes, though very rarely, found. In 1,603

FIG. 8.—Ligament fully drawn out.

cases which I have operated I have encountered conditions which may fairly be regarded as anomalous in not more than half a dozen instances.

9. Occasionally the ligaments are held back by

adhesions, the result of pelvic cellulitis involving the round ligaments.

In seeking the round ligament the tissue pulled out by the hook is each time examined. After a little experience the ligament will be very quickly

with a bit of gauze between the thumb and forefinger of the left hand (Fig. 7). Traction is made while the pouch of peritoneum which forms the canal of Nuck and other tissues are separated and pushed back along the ligament with Kelly forceps,

FIG. 9.—Suturing ligament to aponeurosis of external oblique.

recognized by the characteristics which have been pointed out above. The manipulations should always be gentle and bloodless, care being taken to avoid tearing the structures examined. When a mass of tissue which appears to include the ligament has been engaged by the hook, the tissue should be carefully separated by careful teasing with the hooks. Do not seize the ligament with forceps. (The forceps shown in Figs. 6 and 7 are used only

FIG. 11.—Drawing ligament under aponeurosis of external oblique.

which are not released when the peritoneum is fully stripped back, but remain attached as one pair after another is used. This is necessary to permit of ligation of the stripped-back peritoneum, thus avoiding any possibility of hemorrhage which might result in suppuration of the wound or formation of a hematoma in the broad ligament.

As the peritoneum is stripped off, the ligament

FIG. 10.—Drawing in silk loop with aneurysm needle.

to demonstrate the ligament.) When the ligament is finally found it is caught up on one hook while with the other hook the adherent tissues are gently separated, then the small loop of ligament is caught

FIG. 12.—Ligament drawn out above the external ring.

may be pulled out more and more, until finally so much resistance is felt that the uterus appears to be drawn up against the abdominal wall in the suprapubic region. Measurement of the double loop of

ligament will show it to be seven to nine centimeters in length, representing a shortening of fourteen to eighteen centimeters. No matter how slender the distal portion of the ligament may be, the proximal portion at the point where it emerges from the canal

If the ligament is anchored in this position by attaching the loop of surplus ligament to the anterior surface of the external oblique muscle, the patient may possibly sooner or later develop hernia, as the small intestine will gradually work

FIG. 13 Drawing the end of the ligament under the aponeurosis of the external oblique.

will show a width of half a centimeter to three centimeters.

The ligament having been fully drawn out (Fig. 8), the next step is to attach the ligament at its thickest part to the aponeurosis of the external oblique at the upper angle of the puncture by means of a strong chromicized gut suture passed from beneath the aponeurosis (Fig. 9). A ligature

FIG. 14—End of ligament drawn out through original opening in roof of canal.

is now applied to the shreds of peritoneum held by the Kelly forceps. This closes the canal of Nuck and also ligates vessels which might be a source of trouble.

FIG. 15 Wound in aponeurosis closed.

its way out alongside the round ligament. I followed this plan in my earlier cases and had to operate to repair a small hernia in several cases. To obviate this danger the loop of ligament is drawn back into the canal and pulled up through the aponeurosis at a point five or six centimeters higher up and toward the median line. To accomplish this an aneurysm needle is passed into the canal along the inner side of the ligament and made to emerge at a point five or six centimeters higher up and two or three centimeters toward the median line (Fig. 10). About an inch of the loop

FIG. 16 Skin wound closed.

of ligament is passed through the silk loop and the ligament is drawn back into the canal and up through the aponeurosis. By this means all danger of hernia is eliminated (Figs. 11, 12).

The end of the loop of ligament is again drawn under the aponeurosis of the external oblique and made to emerge at the original opening through which it was first pulled out. Thus the surplus ligament is woven into the aponeurosis of the external oblique, to which it in a few days becomes firmly attached, forming a very secure and permanent anchorage for the ligament, capable of resisting any strain to which it is likely to be subjected (Figs. 13, 14).

The next step is to close the opening in the roof of the canal, for which a curved needle threaded with No. 00 chromic catgut is employed. Care is taken to pass the suture through the end of the loop of ligament so that when the opening in the aponeurosis of the external oblique is closed the ligament is closely applied to the underside. The roof of the inguinal canal is thus reinforced instead of being weakened (Fig. 15).

The superficial fascia is closed with No. 1 plain catgut and the edges of the skin incision are approximated by two or three skin clips (Fig. 16).

Special Advantages of This Method.—The advantages claimed for this method of operation over other methods are the following:

1. The abdomen is not opened, hence there is no shock and no risk of formation of peritoneal ad-

FIG. 17.—Author's spring abdominal supporter

hesions and no abnormal conditions created which might lead to intestinal obstruction.

2. The ligament is so secured that the recurrence of prolapse is almost impossible. In the original method of Alexander the ligament was cut off and attached to the fascia about the spine of the pubes. This method did not give secure anchorage and frequently resulted in complete failure because the ligaments tore loose.

3. The ligament is not injured and no mutilation of any sort occurs, so the patient cannot possibly be made worse, as not infrequently occurs with several other methods.

4. The technique is simple and the operation may be quickly done. The time required is rarely more than fifteen minutes and often only ten or twelve minutes for both sides.

5. The small and superficial incision and the short time occupied by the operation give no occasion for shock.

6. The operation does not give rise to complications in pregnancy as do some other methods. Scores of patients upon whom the writer has operated have afterward become pregnant and in not a single instance has he known the operation to be responsible for miscarriage or any other complication. Pa-

tients sometimes complain of a slight drawing on either side during the early stages of pregnancy, but this symptom soon disappears.

8. The results, when the cases are properly se-

FIG. 18. Spring supporter applied

lected, are better than those obtained from other methods. It is very rare that the operation fails to accomplish everything expected of it. The uterus is not only held in a perfectly normal position, but the patient is relieved of backache and other distressing symptoms. Not infrequently congested or prolapsed ovaries, which are a more or less constant source of pain, become symptomless as the result of restoration of the uterus to normal

FIG. 19.—Same patient shown in Fig. 18 without supporter position. In my early cases failure or partial failure occurred in about 5 per cent. of cases; but the proportion of failures within the last fifteen years has been, I feel very sure, less than 1 per cent.

Failure should not occur if cases are properly selected and the patient given proper after care.

There is no internal method of correcting retrodisplacement which offers any advantages over the external method, and all of the internal methods are objectionable on various grounds.

There is no danger of shortening the ligaments too much. The late Dr. Thomas gave abnormal shortening of the round ligaments as one of the causes of anteversion. This is quite impossible. The only inconvenience which ever results from the operation is a more or less unpleasant sensation of numbness and occasionally neuritis, the result of stretching the sensory nerve which accompanies the round ligament. This is quite rare, however, and may be obviated by cutting the nerve or by exercising very great care in separating it from the round ligament to avoid stretching or bruising it. When the nerve is cut, the patient usually complains for a time of a numb sensation of the pubic region.

Conditions which contraindicate shortening of the round ligaments by this method are the following:

1. Procidencia. The ligaments are not strong enough to sustain the weight of the entire abdominal contents, and a more radical procedure is necessary.

2. The absence of symptoms as in cases of retroversion of long standing in which the uterus is small and free from disease, as often noted in women who have passed the menopause.

3. The presence of adhesions of the uterus, tubes or ovaries either to the pelvic walls or to other pelvic viscera, unless very slight. Slight adhesions may sometimes be broken up by manual manipulation, and in such cases the operation may succeed. When adhesions are suspected, however, it is a wise plan to submit the patient to a thoroughgoing x-ray examination by an expert roentgenologist to ascertain the extent of the adhesions and the organs involved. When adhesions are found, or evidence of serious disease of the appendages, the abdomen must be opened. After dealing with whatever condition requiring attention may be present, the ligaments should be shortened by the method above described.

After Care.—1. The patient should be kept in bed or in a reclining position for ten days or two weeks, but may go out in a wheel chair after the first day.

2. The lever pessary applied at the time of the operation is retained for three or four months.

3. A spring abdominal supporter is adjusted when the patient gets upon her feet and must be worn constantly except at night, until the abdominal muscles become strong enough to support the viscera (Figs. 17, 18, 19).

4. The bowels must be trained to move normally, that is, three times a day, or after each meal and without straining. This should be accomplished before the operation, so that the ill effects arising from constipation following the operation may be avoided.

5. The abdominal muscles must be developed to enable them to support the abdominal viscera in a normal way. This must be accomplished by systematic and carefully graduated exercises. Among the best of these are exercises taken with the body resting on an inclined plane, the head lower than the feet. For patients who are too feeble to take these exercises, automatic exercise by means of the sinusoidal electrical current may be employed for a time to secure sufficient development of the muscles

and possible more vigorous voluntary exercises later.

6. The corset and tight bands must be discarded definitely and permanently.

The patient must live the "simple life," and must make the care of the health a matter of serious and constant concern. It is especially important that she should understand that the operation alone may not effect a permanent cure, but that with her thorough cooperation it makes a permanent cure possible.

REMARKS ON ESOPHAGEAL OBSTRUCTION, WITH SPECIAL REFERENCE TO CICATRICAL STENOSIS, DIVERTICULUM, AND FOREIGN BODIES.*

BY EDWARD W. PETERSON, A.M., M.D.

NEW YORK

WE may classify esophageal obstruction, with reference to its origin, as: (1) congenital, (2) cicatricial, (3) obturation, (4) compression, (5) malignant, and (6) spasmodic. Congenital strictures and diverticula of the esophagus have been mentioned, but very little reliable information concerning them has been recorded in the literature. The most frequent congenital malformation shows itself in some form of communication between the esophagus and trachea or bronchus. Such a condition is necessarily fatal. Cicatricial obstruction is generally due to the ingestion of caustic acids or alkalis or boiling fluids; cicatrization may also result from peptic, typhoidal, syphilitic, or tuberculous ulceration. Obturation obstruction may be due to the presence of certain tumors or to the swallowing of foreign bodies, which lodge and block the tube. Compression obstruction may be caused by diverticula, aneurysm, tumors of the thyroid gland, by bronchial or mediastinal growths, etc. Malignant obstruction may be due to any of the types of cancerous growth; epithelioma, however, is the most common variety. Spasmodic obstruction is seen in neurotic individuals, is often intermittent in character, and is due to some reflex source of irritation.

Anatomy.—The esophagus is a musculo-membranous tube, 9 to 10 inches in length, commencing in the middle line, opposite the sixth cervical vertebra, then deviating slightly to the left as far as the root of the neck; thence to the fifth dorsal vertebra it gradually returns to the middle line; finally it turns again to the left, at the same time passes forward to pierce the diaphragm, and, after an abdominal course of half an inch, enters the cardiac end of the stomach, opposite the upper border of the body of the eleventh dorsal vertebra. The lumen of the esophagus is narrowed at the commencement, $2\frac{3}{4}$ inches below this point (opposite bifurcation of the trachea) and where it passes through the diaphragm. The diameter of each of these points is a trifle over $\frac{1}{2}$ an inch (14 mm.) and the diameter elsewhere is about $\frac{3}{4}$ of an inch (17-21 mm.).

Structure.—The esophagus is composed (1) of an external envelope of loose areolar tissue; (2) of a muscular layer composed of superficial longitudinal and deep circular fibers (they are striped fibers above and smooth below). The longitudinal fibers are deficient in the upper end of the esophagus posteriorly; (3) of a cellulofibrous and glandular layer; (4) of a mucous layer presenting folds, papillae and stratified epithelium.

*Read at a meeting of the N. Y. Post-Graduate Alumni Association, March 14, 1916.

Relations.—The following relations are of surgical importance: The esophagus in nearly all its course is in close contact with the front of the vertebral column. In the neck the trachea is immediately in front of it, and in grooves at each side between these two structures run the recurrent laryngeal nerves. The left lobe of the thyroid is also in front of the gullet. Laterally it is in relation to the lobes of the thyroid gland and the carotid vessels, particularly on the left side. In the thorax it has the left bronchus, left bronchial glands, pericardium, and left auricle in front of it, while the two pneumogastric nerves form a plexus on it. The thoracic duct for the greater part of its course lies behind and to the right of the esophagus; opposite the fourth dorsal vertebra it crosses behind it, so as to lie to the left in the superior mediastinum. The aorta lies to the left of the esophagus above and crosses behind it to the right just above the diaphragm.

General Remarks.—Before the advent of the esophagoscope and the *x*-ray into the field of esophageal surgery, the diagnosis of esophageal lesions was largely a question of guesswork and the treatment a matter of blind, unscientific haphazard. With these aids, however, the diagnosis is relatively simple, differential diagnosis is seldom difficult, and treatment is far more satisfactory and certain. When a patient suffers with dysphagia, before making the routine physical examination it is well to bring out the following points in the history of the case, as they are helpful in making the differential diagnosis: the age of the patient; the date and character of the onset and the subsequent course of the symptoms; whether corrosives or foreign bodies have been swallowed; whether the individual ever had syphilis, severe typhoid fever, or marked digestive trouble, with the accompanying dysphagia; whether there ever occurred dyspnoea, dull boring pain in the vertebrae, ribs or sternum, or regurgitation of material mixed with blood, pus or fragments of a neoplasm.

In every case of organic obstruction of the esophagus there are three constant symptoms, varying in degree, of course, with the nature and extent of the stenosis, namely, *increasing dysphagia, persistent regurgitation and progressive inanition*. In the early stages dysphagia accompanies the taking of solids and gradually increases until soft food and finally liquids are swallowed with difficulty. Regurgitation may be immediate or may occur some time after the ingestion of food or liquids, depending on the tolerance and capacity of the esophagus above the point of obstruction. Inanition may be due to starvation alone or to insufficient nourishment for the needs of the economy—plus toxemia. When

these symptoms occur it is an easy matter, by means of bougies, the *x*-ray and the esophagoscope, to determine the presence, the location and oftentimes the exact nature of the occlusion. The introduction of flexible bougies will establish the site

FIG. 1—Carcinoma of esophagus

FIG. 3—Cardiospasm

of stricture and the patency or non-patency of the canal. Begin first with large instruments and gradually decrease the size, until one is passed or until the non-patency of the esophagus is established. The greatest caution and gentleness should be observed in the efforts; absolutely no force should be exerted, for it is very easy to penetrate the wall of the gullet and thereby to set up a fatal inflammation of the mediastinum. One should not be satisfied with a single examination, but with instruments of various size, and with the head of the patient in different positions, repeated attempts should be made to pass the obstruction. The *x*-ray is a most useful diagnostic aid, and through its use one can often obtain accurate knowledge of the location of the stenosis and of the caliber and course of the esophagus above. It is invaluable, too, in locating foreign bodies, such as coins, false teeth, pins, needles, bones, etc., which may become lodged in the esophagus. Esophagoscopy should always be conducted by an expert, otherwise the examination is unsatisfactory and not without danger. In skilled hands it is possible through the use of the esophagoscope to obtain an accurate picture of the esophagus, to establish the presence of a new growth, of a foreign body, of ulceration, cicatrization, spasm, extra-esophageal pressure, etc. It is also possible through this instrument to remove tissue for examination and to perform special operations under the direct guidance of the eye. I wish to acknowledge

FIG. 2—Carcinoma of esophagus, with fistulous tracts communicating with bronchi

FIG. 4—Cicatricial stenosis due to the effects of caustics

my indebtedness to the consulting esophagoscopists who have given me invaluable aid in the management of certain of my cases.

Benign Cicatricial Stricture.—As has been stated, cicatrization may follow any variety of ulceration,

but usually results from the ingestion of caustic acids or alkalis. It is generally agreed that, before any treatment is started, the burn should be allowed to heal. This can be determined only with the esophagoscope. If the burn is not deep and

ever, that cicatricial strictures are prone to recur, therefore vigilant supervision must be maintained in every instance until such tendency has disappeared. Electrolysis, in selected instances, has given good results in the hands of others, but I

FIG. 6. Cicatricial stenosis due to the ingestion of lye.

cicatrization is not extensive blind catheterization of the esophagus and gradual dilatation will be followed by good results. If catheterization of the esophagus is difficult it had best be done through the esophagoscope, under the direct visual guidance. Often the opening is eccentric and is difficult to find. Many yielding strictures where instruments could not be passed blindly have been successfully dilated through the aid of the esophagoscope. Where the stricture is hard, unyielding and tortuous, it is best to do a preliminary gastrostomy. Then if a filiform bougie can be passed from above or below, or a thread washed through the stricture, one has control of the situation. Internal esophagotomy without a guide is a very dangerous operation. The "Abbe-Dunham" method of chafing through the stricture with a string or linen fish line, a prelimi-

FIG. 7. Coin in esophagus.

have had no experience with it. I have encountered no case of impermeable stricture, and, judging from the testimony given at the Twenty-fifth Congress of the French Association of Surgeons, it is very rare. When the stricture is absolutely impermeable, one can do a simple valvular gastrostomy, which is the measure generally resorted to. If the stricture is in the cervical esophagus, an external esophagotomy can be done; if at the cardia, esophago-gastrostomy is the operation of choice; if in the thoracic esophagus, esophagectomy or esophago-jejuno-gastrostomy, the operation of Roux might be attempted.

Pharyngo-esophageal Diverticulum.—This defect, which is really a hernia at the posterior pharyngo-esophageal junction, manifests itself in middle or advanced life, most often in male subjects. Dysphagia develops very slowly, and may be accompanied by a sense of fulness or an actual tumor in

FIG. 8. Pharyngo-esophageal diverticulum.

nary gastrostomy having been done, is probably the safest way of doing an internal esophagotomy. I have used this method with success several times.

The measures mentioned will succeed in the majority of instances. It must be remembered, how-

FIG. 9. Open safety pin in the esophagus.

the neck. If a tumor is present it can be made to disappear by pressure or regurgitation; the pressure of the pouch on the pneumogastric nerves and the recurrent laryngeal branches produces an irritative cough. All of the patients I have observed have had

more or less bronchitis. Food collecting in the diverticulum decomposes and causes the breath to be very offensive. There is always present the danger of acute inflammation developing in the sac. Malignancy is another complication which may occur in these cases.

The radical extirpation of a diverticulum is not a technically difficult procedure, but owing to the poor condition of and the complications present in sufferers from this affection, the operation is a serious one. One of the greatest dangers is from the anesthetic. My preference would be for local or gas-oxygen or rectal anesthesia. Ether by inhalation is badly borne and is often followed by pneumonia. Before operation the mouth and teeth should receive the most careful attention and the pouch should be washed out thoroughly with a mild antiseptic solution. Before cutting away the sac a large bougie should be introduced into the esophagus, in order to avoid the removal of too much tissue, with subsequent narrowing or stenosis of the first portion of the esophagus. During the operation avoid any leakage into the tissues of the neck. My plan has been to apply a crushing clamp, to cut away the sac, to carbolize the stump, then to introduce the first row of chromic gut sutures before removing the clamp, and finally to bury the first suture line with a second

FIG. 9.—(1) Large pharyngo-esophageal diverticulum successfully removed from man, aged 49 years. (2) Pharyngo-esophageal diverticulum successfully removed from a woman, aged 66 years.

row of catgut sutures. The neck wound should be drained. After operation give the esophagus rest for forty-eight hours by allowing nothing by mouth. Give fluids by proctoclysis or hypodermoclysis or infusion. By observing the precautions mentioned there has been no leakage or infection in the cases operated upon by me. The one fatality is believed to have been due to the ether inhalation anesthesia.

Foreign Bodies in the Esophagus.—A great variety of objects have been known to lodge in the esophagus. They may partially or completely block the canal, or wound it severely or actually penetrate its wall. Smooth bodies which at first do but little damage, may from pressure produce ulceration and later alarming esophagitis or even perforation. It is never safe to follow an expectant line of treatment; foreign bodies should be removed at the earliest possible moment. Radioscopy may be used with advantage both in locating and removing the offending object. The horse-hair probang of Weiss and the coin catcher of Gräfe, instruments much condemned in recent years, still have a definite field of usefulness in the removal of certain smooth bodies, such as coins, buttons, etc. The blind removal of sharp objects, however, is absolutely contraindicated, for the damage incident to such at-

tempts may prove irreparable. Under such circumstances the foreign body should be located and its removal accomplished through the aid of the esophagoscope. Through this instrument the ring of an open safety-pin can be seized with special forceps, the pin carried into the stomach and there turned, after which it can be withdrawn with comparative ease and safety.

I have personally encountered and treated either radically or palliatively a number of cases of esophageal obstruction, most of which belonged to the cicatricial stenosis or foreign body group. Cancer is probably the most frequent affection of the esophagus. Törek's resection of the thoracic portion of the esophagus for malignancy was the first successful operation of its kind in the human subject. It leads one to hope that in the future, early diagnosis and prompt radical treatment will be attended by a fair measure of success in this most difficult and discouraging field of surgery. My own experience in this class is limited to the performance of palliative gastrostomy in late cases. I have treated six cases of cicatricial esophageal stenosis, due to the ingestion of corrosives, and during my interne service in the babies' wards of the Post-Graduate Hospital I had an opportunity, under the supervision of Drs. Samuel Lloyd and Theodore Dunham, to study six additional cases. There were two deaths in my series. In the first instance, after very careful efforts to introduce bougies, pneumonia developed and resulted fatally. It was not thought at the time that the gullet had been perforated, but as autopsy was not allowed this question could not be determined. Pneumonia is an occasional complication of esophageal instrumentation, and this danger should always be borne in mind. The second death was unquestionably due to starvation; a simple gastrostomy was done, but the patient died of exhaustion a few hours later. Three cases were successfully treated by gastrostomy and internal esophagotomy. A fourth case yielded to gradual dilatation with bougies. One interesting case of obturation obstruction, in an infant, was due to the presence of a fibrous polyp, with a long pedicle, springing from the pharynx. Occasionally the growth would be swallowed, producing alarming symptoms, such as choking, cyanosis, and threatened suffocation. The removal of the polyp was easily accomplished and brought about immediate relief of the symptoms. Another obturation case was in a little girl who some time before had accidentally swallowed lye. After swallowing an improperly masticated piece of meat, there was for two days occlusion of the esophagus, even to the passage of liquids. After the removal of the meat, which was lodged about opposite the sternal notch, a cicatricial stricture was found at this point, which was successfully treated by gradual dilatation with flexible bougies. Three cases of pharyngo-esophageal diverticulum have been treated by radical removal of the pouch and esophagoplasty. One of these cases died of double pneumonia in less than forty-eight hours after the operation; the other two are alive and well to-day. Among the foreign bodies which I have removed from the esophagus without accident or ill effects are the following: a chicken bone, a piece of meat, a pin, an open safety-pin, a public school medal and a number of coins. But one case of cardiospasm has come under my care. This spasm developed in a man who was being treated for amebic colitis, and disappeared spontaneously after a sea voyage. Also I have had but one case of congenital obstruction of

the esophagus. A gastrostomy was performed, but the infant died on the fourth day. Autopsy was not allowed, so the nature of the malformation could not be determined.

The accompanying x-ray pictures illustrate some of the types of esophageal obstructions.

525 PARK AVENUE

AUTOSERUM IN THE TREATMENT OF CANCER*.

BY CAPTAIN OWEN PAGET, M.D.,

FREMANTLE, WEST AUSTRALIA.

MÉDECIN CHEF, HÔPITAL MILITAIRE 37 A, DIEPPE, FRANCE

In previous publications in Australia and America I have attempted to show that "Epithelial cells are if not the most important at least probably the most often employed structures not only to protect and immunise us against disease, but also to cure disorders already in evidence." The importance of the intestinal mucous membrane is manifested by the universal appreciation of the necessity of a proper physiological activity of the bowels.

Again the exanthemata which represent the majority of the infectious diseases are usually cured by an appeal to the skin. And lastly my own work, which has been specially directed toward the nasal mucous membrane, seems to prove that this structure has not only protective and immunising, but also curative powers against tuberculosis.

The belief that epithelial cells have curative properties against disease suggested the possibility of stimulating these cells by a blister and injecting the resulting fluid into the subcutaneous tissue of a person suffering from cancer. This disease as is well known is characterized generally by a depreciation of health, and locally by a persistent and abnormal infiltration of epithelium-like cells.

It is this combination of conditions which it is important to appreciate, for the body may at any time be disabled by a general depreciation in health without any apparent change in the epithelial cells. On the other hand an abnormal if not persistent proliferation of epithelial cells may occur, as in the simple tumors, without any corresponding debility. The word "cancer" is intentionally employed in this paper, as it is essential when viewing a proposition from a fresh standpoint to unfetter the mind from conventional classifications and methods of thought. As Dr. Pettit pithily expresses it—"Le pathologie du cancer, c'est la blague."

In patients suffering from cancer who are treated by the method mentioned, the beneficial influence is first noticed in an amelioration of the general cancer cachexia, and not for some time in the growth itself.

The first local examination of the case given in this paper was intentionally not made for one month. Although the patient's general appearance at the end of that time was distinctly improved, the best that could be said for the growth was that it was less rigid, and that it was easier to make a thorough examination without fear of injuring the patient by provoking hemorrhage or fear of rupturing the bowel.

In this connection I wish to quote from Sir James Paget's "Pathology of the Cancers" a pas-

sage with reference to disproportion between cachexia and growth. He says: "Cancerous disease exemplifies a frequent event in the history of specific diseases; namely that when the morbid material is most intense and acute in its action, when it most manifestly affects the constitution, it may produce the least indications of local morbid influence." Again he says: "I think malignant tumors are local expressions of some specific morbid states of the blood." It seems as if the keynote of the cancer problem lay in these two definitions.

Supposing that a cancerous growth is an expression, however incompetent, of resistance to some virus, which virus is not necessarily the same in all cases, then after all the growth is a condition akin to an abscess or violent inflammation, and cannot justly be designated a disease, but rather a symptom. It will be seen to what extent in the following case these theories receive corroboration.

Patient's name—Ferdinand Piette, a private in the 25th Territorial Regiment, born January 15, 1873. Admitted here August 5, 1915. Had felt ill for about 18 months before admission. Had consulted a medical man for hemorrhage from the bowel at the commencement of the war, August, 1914, but was not examined. He was transferred from another hospital to this one as a case of enterocolitis with dysentery and passing of blood. General appearance on admission—haggard, cachectic, and slightly jaundiced; carried himself with a stoop. Each time he desired to urinate, it was necessary to go to the closet, as the bowels wanted to act at the same time. Appetite poor and capricious. Passing large quantities of blood per rectum, also much mucus. Motions otherwise evil-smelling, watery, and very frequent. Some pain on urination. Weight on August 26 was 135 French pounds.

The case was examined by Dr. Pettit of Paris, a former pupil of Professor Metchnikoff's, and consulting surgeon for this military district; Dr. Dupont in charge of a French Military Hospital; and Dr. Oliver Walker, attached to this hospital.

Diagnosis: Large inoperable carcinoma of the rectum. Wassermann reaction negative.

August 21. Treatment was begun. September 18. The growth is less rigid. It is easier to make a thorough examination without fear of injuring the patient. There is a slight gain in weight. There has been less hemorrhage from the bowel, and less trouble with urination. General appearance of patient improved. He feels stronger and objectively does not look so haggard and flabby. Tendency to jaundice is distinctly lessened. September 22. Patient examined by Dr. Dupont for first time. Diagnosis of carcinoma of rectum confirmed. October 3. Growth is less rigid, and also less in size. October 9. Distinct improvement. October 16. Examination by Dr. Pettit, Dr. Walker, and myself. General condition much improved, also growth smaller in size. October 23. The growth now feels like a uterus with torn cervix. Finger, after passing through external os, moves freely inside. Whole growth has some swing like a uterus, but still attached behind. At one place growth passes into normal tissues without an edge. October 30. Opposite the former place is another part where growth passes into normal tissue without an edge. Less like a malignant growth and more like an adenoma. November 5. Weight is now 147 French pounds. This is an increase of nearly one stone (English) since August 26. Dr. Dupont made another examination and said: "In my opinion since I saw the patient (6 weeks) the tumor has diminished about a quarter. It is much less hard, and the finger now penetrates easily the contraction which did not allow a proper examination. The general appearance of the patient is better, and especially his color. He looks better." December 6. Examination by myself. Apparently general improvement; especially the character of the mucous membrane covering the growth seems more natural. A natural moisture. Gain of 1 lb. since last examination.

Before this date patient had lost all general symptoms of his disorder except occasional hemorrhages, mostly very slight in character. His general condition and strength were enormously improved. The motions, no

*A lecture delivered at the Medical Schools, Cambridge, England, January 17, 1916.

longer offensive, are usually semi-solid and occasionally formed. There is no longer mucus in the stool. He does not sleep too soundly at night. This may be accounted for in part by the blisters, which irritate and in addition prevent sufficient exercise. He is rather stale as a result of his surroundings. From a surgical point of view he is now easily operable. The growth is apparently quite free from the bladder in front and gives the impression that it can be pulled down to the anus.

December 15. (Dr. Walker's examination.) Growth smaller. Much more movable now. *December 16.* Dr. Pettit's examination and report. Comparison between present condition and when seen four months previously: "Lorsque j'ai examiné Piette le 15 Aout 1915 j'ai constaté au toucher rectal une tumeur constituée par des saillies volumineuses reposant sur une base indurée et encubrant la lumière du rectum. Les saillies étaient dures, comme du cartilage, et le pulpe de l'index ne pouvait pénétrer au dessus de la tumeur ni-même s'engager dans le rétrécissement. L'état général était mauvais—amaigrissement, faiblesse. Je demandai une réaction de Wassermann qui fut négative. Je revis le malade le 16 Decembre 1915. Etat général bon. Forces en grand progrès. Embonpoint très satisfaisant. Au toucher le doigt pénètre facilement dans le rétrécissement maintenant plus large, et en dépasse juste la limite supérieure. Les végétations sont moins grosses et plus souples. La base indurée est beaucoup moins dure. Ces modifications sont particulièrement nettes vers la partie postérieure du rétrécissement."

December 27. Although no injection has been given since December 17 progress is still satisfactory. *January 10.* Improvement in growth still satisfactory, weight and general condition remain the same. There has been no treatment for nearly one month.

In my observations on tuberculosis, the conclusions arrived at were that the prevention, immunity, and even cure of the disease are dependent on the physiological perfection of the epithelial cells of the nasal turbinates and sinuses, and to a lesser degree the lining cells of the intestinal mucous membrane. The natural action of epithelial cells in resisting and immunising against disease is quiet though persistently in evidence. It is as much a physiological function as the digestion of food or the secretion of sweat. More so in fact. We are resisting disease every moment of our lives. We do not eat or sweat all the time. I think this point should be very clearly understood and appreciated. Medical thought is too liable to regard disease as a sudden invasion. It may be such, but it is much more a breakdown of constant resistance.

In tuberculosis, with this breakdown of resistance and immunising capacity, the body becomes invaded with tubercle bacilli. Once attacked, it may yet apparently withstand the disorder, but is dependent on an inefficient leucocytosis, and is in a state of unstable equilibrium; so that a strain or a blow causes an abscess perhaps in the hip, perhaps elsewhere. It results from this that tuberculous infection is the result of physiological imperfection.

In cancer the disease is probably in similar fashion held in check by the physiological action of epithelial cells, but when this capacity breaks down, it is not a pathological leucocytosis which arises, but an erratic epithelial growth. The exanthemata are the best expression of the importance of epithelial cells. In these diseases there is not only the objective appearance of the running nose and injected conjunctiva, the subjective sensations of improvement with free action of the bowels and skin, but there is further the rash, that most emphatic expression on the part of nature to utilize the epithelial cells of the skin in an attempt to cure disease.

If, as seems infinitely probable, the cancer virus

circulates in the body and with the blood, it is reasonable to suggest that nature seeks to deal with this agent in a manner similar to that employed in the infectious diseases. Drawing a comparison with tuberculosis the occurrence of the cancer virus in the tissues is already an assumption that normal epithelial action has broken down. It is hardly conceivable otherwise, for we must be constantly exposed to cancer virus, which is as constantly held in check by some action, which experiment seems to show is epithelial.

The cancer virus once in the system, the body is probably still capable of some resistance, but as in the case of tuberculosis is in a state of unstable equilibrium. If now the vitality of any region is lowered either by constant irritation, as in the case of the smoker's lip, or as in the case of a woman from a blow on the breast, or even from causes imperceptible to us, then there results a local proliferation not of leucocytes, but of epithelium-like cells. It is probably false to regard this as an hypertrophy due to increased work. It is an excessive incompetent activity due to an irritating stimulus, and as such knows no bounds or limitations. The only apparent difference therefore between the abscess of tuberculosis and the cancerous growth, outside the fact that they are formed of different varieties of cells, seems to be our capacity to deal with them surgically.

An abscess by constantly enlarging and eating away the body is as capable of destroying it as a cancerous growth, but apparently, in some way very inexplicable, it changes its character when it discharges its contents.

It is well known that cancer attacks us at that time of life when common experience suggests that our physiological functions are naturally diminishing. These activities are still further depressed by the demands of civilized existence, which with its monotony and worry psychologically depresses them. While the cares and anxieties of our social system are so innumerable that mankind is never free from them, the influences of the nervous system on epithelium are enormous. Its impulses excite us to cry when distressed, inhibit salivation and digestion at times of fear and anxiety, and cause the skin to be blanched and faded, when the body is exposed to excessive strain. Hypercivilization with its punctualities and duties demands a restraint of physiological impulses, and hence is a potent factor of constipation. This, in turn depresses the normal activities of the cells lining and forming the intestines. With their lowered capacity the cells permit the transmission of bacteria, which apparently are enmeshed in Lane's adhesions. These further lower the capabilities of the intestine, and are regarded in surgical circles as precursors of cancer.

Clothing again by its character must often be inhibitory to the normal action of the skin. It was recognized in former days that chimney sweeps whose skins were in a perpetual state of irritation or inhibition through soot were peculiarly liable to cancer, and parliamentary legislation was brought to bear to remove this danger from a section of the people.

If the view is taken that any attempt to treat cancer should be directed against neutralizing cancer virus, it is not necessary to expect any speedy or immediate retrocession of the growth. In fact it is surprising that it is affected at all. There is possibly no longer a reason for this artificially stimulated structure, but once established it is diffi-

cult to expect otherwise than that it will remain, or at best become encysted. However the growth does recede, and gradually tends to return to the natural condition of the tissues. Now there is seemingly no attempt at cicatrization or fibrosis, but on the return to the normal there is a stage where to the touch at all events the growth feels adenomatous.

Is it possible that the difference between a simple adenoma and a malignant growth is that the former having accomplished its purpose becomes encysted and shut off, whilst the latter, never able to destroy the irritant virus, itself destroys the host?

Before taking too definite a view, it is advisable to compare epithelial cells in their resistance to disease with mesoblastic cells and especially leucocytes engaged in a similar endeavor. It must be borne in mind that epithelial and mesoblastic cells may be in action simultaneously.

Epithelial Cells.

1. Constant physiological action in protecting and immunising us against disease.
2. The body attacked by a virus the reaction is expressed by erythema and rashes as in the exanthemata.
3. Under certain circumstances the virus is not quickly or entirely destroyed. It is however shut off from the rest of the body by collections of cells. *e.g.* The adenomata.
4. Sometimes the character of the cells is such as to prevent them becoming encysted. *e.g.* The papilloma and the rodent ulcer.
5. Sometimes the cells infiltrate and irritate the tissues. They are in addition both destructive and liable to destruction. *e.g.* The cancers.
6. A rare modification of the last. The scirrhus cancer which is cured.

Mesoblastic Cells.

- Probably constant similar action but of lesser quality.
- Under similar circumstances reaction is expressed by the various inflammations.
- Under similar circumstances.
- The gumma and the tubercle.
- Similarly, the sarcomata.
- Similarly, noma, some soft chancres, and abscesses.
- Similarly, the encysted (cold) abscess.

If the hypothesis is entertained that the reason why epithelial cells behave in certain ways is because they have curative properties, one's interest is aroused as to what powers they have to move from place to place. My own knowledge of present day pathological histology is so limited as not to permit me to discuss the matter with any degree of freedom. But reading Mr. Sampson Handley's book on Cancer of the Breast, the impression left is that there are not only considerable movements of cancer cells in the lymphatic spaces in disease, but that probably epithelial cells circulate in the lymphatic circulation during health.

After all, is it essential that epithelial cells be fixed, and do we know positively where all the cells in the blood and lymph come from? Certain it is that epithelial cells can be implanted and take root in foreign soil with great ease, as is shown in the surgical skin graft.

This paper is not a clinical one, but there is a practical aspect. The case was diagnosed as one of inoperable cancer of 18 months' duration. Four months from the commencement of treatment the general health is excellent. The patient has gained

14 pounds in weight, and the growth is very much smaller.

The physiology and pathology of tuberculosis and cancer have been shown in this and previous papers to be simpler than is usually assumed. A future paper will deal with the results of treatment in a series of cases already started, and will attempt to explain the extraordinary phenomenon of the apparent disappearance of the growth after discontinuing the treatment.

My sincere thanks are due to the members of the French medical profession with whom I have been brought in contact for their invariable kindness and courtesy, and for their scientific and open-minded attitude with regard to my investigations. It is a pleasure to mention with them Miss Olivia Walker, M.B., who is at present attached to this hospital, having come all the way from Trinidad to lend her services to the wounded.

THE VALUE OF MODERN AIDS IN SURGICAL DIAGNOSIS.*

By JOHN T. HOWELL, M.D.,

NEWBURGH, N. Y.

THAT the nineteenth century saw the most remarkable progress in surgery of all times was due chiefly, as we know, to two discoveries—anesthesia and the role of microorganisms.

The highly developed senses of those physicians who practised before this epoch had enabled them to discover in a wonderful way many obscure subjective symptoms which to-day might baffle us if we were limited only to such methods of diagnosis. However, while we continue to make examinations by physical methods, we have the assurance that there yet remain in reserve the laboratory, the x-ray, and the various instruments of precision with which a diagnosis can be confirmed. Modern surgery has had many claimants for the honors of its marvelous development, but the test of time has left comparatively few worthy of such credit. Besides Morton and Pasteur may be named Hunter, Virchow, Lister, Tait, Koch, Behring, Metchnikoff, Ewald, Boas, Röntgen, and some others, who have revealed the secrets of pathology, bacteriology, hematology, gastroenterology, and röntgenology.

In all of these fields there have been discovered certain pathological, etiological, and functional factors, a knowledge of which is of great assistance in surgical diagnosis—and it is to a consideration of the value of these modern aids that I ask your attention.

The first of these aids owes its origin to the postmortem and cellular pathology conducted by Hunter and later by Virchow. Tait contributed much to living pathology in his original abdominal work incident to surgery of that cavity, and later Horsley, Cushing, Carrel, Crile, Matas, and others have developed the pathology of surgery along many important lines.

Accurate pathological findings may now be depended upon to detect neoplasms from hyperplasia—and in neoplasms, malignancy from benign conditions; also to classify by types, different malignant and non-malignant growths—and in most cases to tell from what tissue originating and from what embryonic tissue derived.

The pathological findings are positive in a dif-

*President's address before the Newburgh Bay Medical Society, Jan. 11, 1916.

ferential diagnosis between Hodgkin's disease and tuberculous lymph nodes; and it is possible to differentiate between syphilitic and tuberculous conditions. Preoperative specimens should be examined whenever it is possible to obtain them, but it is conceded that the examination of frozen specimens at the time of operation is oftentimes not a dependable method.

In cases in which exudates and transudates are present, a study of the character and number of cellular constituents found in the specimens is often of great help in diagnosis, especially in pleural, joint and cystic fluids, and in fluids obtained from the cerebrospinal cavity, which normally contain no cells.

The importance of an early diagnosis in many of these cases is well appreciated. In those cases where there is no living tissue available, a Wassermann reaction, for example, will determine, in a large percentage of patients, whether syphilis be present or not; and where tuberculosis is suspected in children, we have a convenient and reliable test in von Pirquet's reaction. The reaction from old tuberculin, according to the method of Koch, is positive only if there be a tubercular focus, whether active or latent.

These tests are based upon the degree of resistance of an individual to a given disease. A complement fixation test for tuberculosis¹ is being worked out with much promise, and bids fair to be as valuable as the Wassermann test for syphilis.

To Pasteur is due the revelation of the role of microorganisms—undoubtedly the most important discovery in the field of medicine during the last century. Bacteriology has already revealed the secrets of many hidden problems, and the present army of second generation workers is constantly reporting other enemies in the fields of microbes they are exploring.

Of the many surgical infections now traceable to definite microorganisms there can be named: anthrax (*B. anthracis*), actinomycosis (*ray fungus*), erysipelas (*Streptococcus pyogenes*), glanders (*B. mallei*), malignant edema (*vibrio septique*), rabies (Negri bodies), tetanus (*B. tetani*), tuberculosis (*B. tuberculosis*), boils, carbuncles, circumscribed abscesses, and pyemic infections (*Staphylococcus pyogenes aureus*), etc.; and the infection spreading local inflammations with necrosis of tissue, phlegmonous erysipelas, suppurating joints, purulent peritonitis and pelvic cellulitis (*streptococci*, etc.). The abscesses found in the region of the alimentary canal are generally due to *Bacillus coli*. The gonococci may be found outside the genitourinary tract causing peritonitis, endocarditis, meningitis, suppurative pleuritis, and arthritis.

Certain bacilli cocci and some of the specific parasites can be detected in the blood. Examination of the blood cells has become a dependable means of diagnosis and is a ready means of verifying the existence of suppuration in obscure or inaccessible places. The white blood cells and differential counts are of positive value in determining the presence of suppuration, and by noting the degree of polynucleosis one is helped to differentiate between an acute catarrhal and an actual suppurative condition. It is important not to mistake a pus pocket for a malignant neoplasm, as in both there may be a leucocytosis, and it is here as in many other conditions that it is necessary to remember to give full consideration to all other symptoms, both subjective and objective. In gen-

eral the following blood conditions are significant:²

A normal leucocytosis (7-10000) and low polynuclear (60 per cent. — 75 per cent.) are negative of pyogenic infection, but may exist in typhoid, malaria, colics, etc. An absence of leucocytosis may indicate a feeble resistance or that the pus is shut off from the general circulation. A high degree of leucocytosis (80 per cent.) indicates the existence of an intense process; a steady increase of leucocytes, a severe spreading process; a sudden increase generally means a new invasion, while a falling degree of leucocytosis follows evacuation of abscess. A leucocytosis often occurs after hemorrhage.

The number and condition of the red blood cells are of importance as an indication of a cachexia, pernicious anemia, severe hemorrhage, and certain parasitic diseases.

The use of the sphygmomanometer as a register of blood pressure has an important place in surgical diagnosis and is a helpful guide in determining certain surgical conditions resulting especially from injuries to the head or spine, from shock, and in anesthesia.

It should be noted³ that during an operation the blood pressure is apt to show a marked fall—5 mm. or more. Irritation of the large nerve trunks may cause a rise, while if the peritoneal cavity be opened and the viscera handled there will be a reactionary fall. Concussion of the brain during the paralytic stage is generally accompanied by low blood pressure, while in acute compression from clot or fracture the blood pressure is increased. A complicating uremia will also increase blood pressure. High blood pressure in acute peritonitis may indicate a typhoid perforation. It is well to remember that the diastolic blood pressure changes are of more importance than the systolic range. The average normal diastolic range between the ages of 15 and 67 is from 85 mm. to 99 mm. The average systolic range for same period, 110 to 140 mm.

Uranalysis continues to afford valuable aid in surgical diagnosis, and such an examination, it is conceded, should be employed as a matter of routine in all cases, in order to determine not only functional disturbances but also the possible presence of albumin, sugar, acetone, urea, indican, casts, pus, blood, etc. Information thus derived may indicate a choice in the selection of anesthetics, the limitation of the period of operation, subsequent diet, etc. If a further examination be indicated this may be accomplished by the aid of the cystoscope or urethral catheter, thereby determining the existence of vesical or renal calculi, growths, ulcers, etc., and the amount and character of the secretions of each kidney.

In the autumn of 1895 W. K. Röntgen's discovery of the x-ray opened up a most wonderful field for investigation and study of the opaque structures of the human body. In so far as the broadening knowledge goes this discovery of the cathode ray ranks among the foremost contributions to surgery. Of great value was the localizing of foreign bodies, which was found always possible if the substance were sufficiently opaque—observations of the bony skeleton, especially deformities, displacements, and fractures, have been of the most valuable aid in diagnosis, although, as is well known, a critical examination of all radiographic plates is necessary to their correct interpretation. The use of the screen, it is claimed by some authorities,⁴ is much better than plates in determining certain conditions in the thoracic and abdominal cavities, as pleural

effusions and some cases of gastric cancer. There is, however, a greater exposure and danger to burns on the part of an operator in using the fluoroscope, especially from a high power machine. Since the employment of the bismuth meal or a preparation of barium sulphate it has become possible to visualize the gastrointestinal tract in such a way as to make it possible to study its motor and structural changes.

The diagnosis of gastric cancer from ulcer is but relative, but these conditions can undoubtedly be distinguished earlier by the *x*-ray than by other methods. Carmen⁶ claims that an *x*-ray diagnosis can be made in 93 per cent. of cases examined, and Cole⁹ in 89 per cent. by serial plates.

The serial plates have been most successful in abdominal work, but are expensive. However, since one-third of all cases of cancer occur in the stomach, gastric work with the *x*-ray is of greatest value. Haenisch obtained successful diagnosis of stomach conditions by distending it with air. The various conditions of ptosis are rendered evident after the ingestion of a meal of some opaque substance. Hair balls in the stomach have been diagnosed by Barclay and Holland. Duodenal ulcers are shown by the persistence of a spot on the plate. Palefski⁷ advocated the use of the duodenal tube to bring out the upper intestine. It is claimed⁸ that the appendix can sometimes be shown if a radiograph be taken when it is most likely to be distended, about six hours after meals. Large aneurysms, cystic and solid tumors, enlarged kidneys, and abscesses may occasionally be demonstrated clearly, and adhesions of the intestines and adventitious bands have also been successfully shown on some plates. The duodenal cap formed by adhesions with the gall bladder is considered diagnostic of gall stones.⁹ Gall stones (containing calcium) may be recognized in about 30 per cent.¹⁰ of cases, but they must be carefully differentiated from other shadows cast by kidney stones or calcareous glands. Pfahler¹¹ claims that he can show 50 per cent. of his cases by the use of a special technique.

Pyelography, which consists in obtaining an *x*-ray shadow of the renal pelvis and calices, which have been filled with an opaque fluid, has been successfully employed in the early diagnosis of dilatation due to calculus or movable kidney, in growths affecting the pelvis of the kidney, and in calculi in either the pelvis or calices of the kidneys; *x*-ray pictures of bladder stones are uniformly successful, but like other deposits these must be composed of lime or other opaque substance to be brought out clearly. Uric acid calculi can seldom be seen.

Radiographs of the teeth are successful in showing the pus foci of pyorrhea alveolaris, and plates taken of the head and face may reveal obscure collections of pus in some of the sinuses or the mastoid, and sometimes unsuspected fractures of the skull are revealed.

Transillumination is another practical means of discovering retained secretions or pus in the various sinuses referred to.

Time will not permit mention of the bronchoscope, esophagoscope, proctosigmoidoscope, and other special aids to diagnosis, valuable chiefly in the hands of experts. The same is true of the various gastroduodenal tests.

In closing I would emphasize the necessity of obtaining a complete general history and examination of every surgical case before resorting to any of these special aids, which, although valuable,

should have the corroboration of all other diagnostic signs and symptoms if they are to be safely accepted as evidence in the rendering of a dependable final decision in diagnosis.

107 GRAND STREET.

ERYSIPELAS MIGRANS AND MULTIPLE ABSCESSSES IN A SIX MONTHS' OLD INFANT SUCCESSFULLY TREATED WITH VACCINES.

BY LOUIS FISCHER, M.D.,

NEW YORK.

THE literature records a number of cases in which a breach of continuity of the skin cannot be made out, but still we have distinct evidence of erysipelas due to the invasion of the Fehleisen bacillus. This condition is fortunately very rarely seen in infancy.

Fully 50 per cent. of the cases of infantile erysipelas recorded in medical literature have had a fatal termination. I desire to report the following successful case which had continued high fever and symptoms pointing to a general toxemia. In this case there was no macroscopical evidence of the point of invasion as there was no breach of continuity perceptible. The case is interesting because of the severity of the infection, the fact that the whole body suffered from the disease, and that we were dealing with a very high fever from the beginning. The only circumstance in favor of the infant was the fact that it was nourished with human milk, and that it took its food regularly and seemed to assimilate the same.

BABY C.—Six months old, a nursing baby, was seen by me several times in consultation with Dr. S. Hermann of Brooklyn. When first seen the infant had been ill three days. The temperature was 105° Fahr., pulse 168, respiration 80. There were marked cyanosis, vomiting, extreme weakness, and retention of urine. There was a marked erysipelatous flush on the vulva which spread very rapidly toward the abdomen and thighs.

The inflammation on the vulva was of a deep red color. There were thickening and edema, while spreading to the buttocks and up the back we could note a sharply defined edge. There was slight pitting on pressure. The redness seemed to disappear under pressure. The redness was of an erythematous character, uniform and not mottled. The skin was tense and shiny. The surface temperature was raised. The inflammation spread from the buttocks to the back, then to the thorax, and downward to the extremities. From the back it spread to the neck, scalp, and face, closing the eyes. There was marked thickening with swelling which involved the ears, cheeks, nose, and neck. This swelling of the face did not interfere with feeding.

Three or four days after the extension of the swelling from the buttocks to the back, there was a marked diminution in the redness and swelling, but the new areas involved were considerably indurated, tense, and hot on palpation. In three or four days more the scalp, ears, and nose which were swollen became less shiny, and the swelling gradually subsided. With the reduction of the swelling and inflammation there was a marked desquamation. The arms and legs were the

last to be involved. They went through the same process of redness and thickening which lasted four to five days longer.

From the spreading nature of the disease, I believe we can classify this case as one of erysipelas migrans—the wandering type of erysipelas.

During the course of the disease the behavior of the infant was remarkable. As previously stated, it was a breast-fed infant who took its nourishment at the regular intervals, with the same appetite as when in health. The stool was well digested and normal in appearance and there seemed to be no evidence of faulty metabolism. The infant seemed therefore to offer good resistance to its infection, notwithstanding the fact that the temperature remained unusually high.

Diagnosis.—Erysipelas migrans of unknown origin. The sanitary surroundings were perfect. No apparent reason for the infection. The lungs were normal, although the pulse-respiration ratio was markedly disturbed and suggested a pulmonary complication.

The leucodescent light was tried three times a day by Dr. Hermann the rays covering the affected area. Ichthyol ointment also was used without markedly diminishing the inflammation. The local application of lead and opium wash, and other evaporating lotions did not seem to reduce the temperature nor to modify the inflammation. The swelling continued in spite of the continued use of these lotions.

I have seen excellent results during my service at the Willard Parker Hospital from the constant use of a saturated solution of magnesium sulphate used locally. In this case it did not modify the inflammation. The erysipelas continued to spread, so the light treatment was discontinued and serum treatment was begun.

There was marked fluctuation in the labial swelling and a drop of pus examined showed the presence of *Staphylococcus pyogenes aureus*.

On the fourth day of illness an injection of 75,000,000 germs of a streptococcus stock vaccine was given. On the sixth day, 50,000,000; on the seventh day, 60,000,000; on the ninth day, 70,000,000 germs were injected. A decided improvement was noted. By this time we had obtained an autogenous vaccine and gave the first injection of 100,000,000, a second injection of 100,000,000 plus 100,000 the following day. On five successive days injections, each 100,000 more than the last, were given.

On the fifth day following the first vaccine injection an abscess on the right labium major was incised. A general multiple furunculosis on the arms, scalp, thighs, and back appeared in rapid succession. A general pyemia existed. In addition thereto a pustular eruption appeared on the face and head. Several dozen of these were incised and pus evacuated.

Summary: A reduction of the temperature was tried with lukewarm colonic flushings, also by means of tub baths, but without avail.

Ichthyol was useless, likewise magnesium sulphate in a saturated solution. Neither seemed to reduce the inflammation or the temperature.

Breast feeding was continued throughout the disease and continued after complete recovery.

The streptococcus vaccines, both stock and autogenous, brought down the temperature by lysis, and this seemed very effectual in modifying the erysipelas.

It is difficult to state whether or not the migration of the staphylococcus through the circulatory tract was responsible for the multiple furunculosis, the numerous pyemic abscesses, and the pustular eruption on the face and scalp.

The large dosage of the vaccines given and the non-toxic results therefrom show the tolerance this infant had for the same.

The child made a brilliant recovery, and is perfectly well to-day.

I am indebted to Dr. Hermann for the clinical details of the above-mentioned case.

In addition to the vaccine used by me in the case reported other methods of therapy have recently been tried. Kaiser of Rochester reports a case of a six-year-old child treated with convalescent blood from a nursemaid. Seven ounces of the citrated fluid were injected into the muscles with excellent result. This method of using convalescent blood has been tried in the scarlet fever wards of the Willard Parker Hospital during my service, and reported by Drs. Park and Zingher. Definite conclusions based on the cases treated can hardly be given, although excellent results were frequently seen.

Diphtheria antitoxin has its advocates. It has proven of no value in many cases in which it was used during my service covering many years at the Willard Parker Hospital. In addition to the serum I was always compelled to use local remedies to modify the erysipelous edema.

As to the value of local applications they serve well in many cases and disappoint in many more. The internal treatment with iron so frequently advocated has served me in some cases and been found wanting in others. I am therefore satisfied that we cannot ascribe virtues to iron in all cases. After all we are compelled in the light of our present knowledge to use one drug after another, and use vaccines when procurable. No one would consider the treatment of a case of febrile erysipelas without clearing the gastric and intestinal tract, thus eliminating toxins through the intestines.

CEREBRAL SYPHILIS OF RECENT ORIGIN WITH REMARKS ON THE THERAPY.

BY MORRIS J. KARPAS, M.D.,

NEW YORK.

CHIEF OF CLINIC OF NEW YORK NEUROLOGICAL INSTITUTE (THIRD DIVISION); CLINICAL INSTRUCTOR IN NEUROLOGY, CORNELL UNIVERSITY (MEDICAL DEPARTMENT); FORMERLY ASSISTANT RESIDENT ALIENIST, BELLEVUE HOSPITAL, NEW YORK.

SYPHILITIC affection of the nervous system of comparatively recent origin is of relatively infrequent occurrence. In fact, at one time such distinguished authorities as Fournier and Huebner were of the opinion that nervous manifestations during the first stage of syphilitic infection were unusual.

In going over the literature which is so well handled by Nonne in the last edition of his book, "Syphilis und Nervensystem," we find various references made to isolated cases of cerebrospinal syphilis in which the etiology was of recent origin. Lefèvre's case of facial paralysis developed during the secondary symptoms. In 1864 Kühn, Bahr, Vidal, and Lancereaux described cases of syphilitic nervous diseases occurring within a few months of the primary infection. In 1879 Fournier and Troisier, together with the statistical documentary evidences of Braus, Lang, and Naunyn, unanimously concurred with the idea that in the majority of instances the nervous system usually becomes affected during the first year of luetic infection. Cases of unusually early involvement of the nervous system have been observed and reported by various investigators. For instance, Gilles de la Tourette's patient developed a severe syphilitic condition of the brain and cord only two months after the primary lesion. This author alludes to a patient of Fournier who had well-defined symptoms three months after luetic infection. There are other cases on record as follows:

Author	Case	Within the Period of Infection.
Kreibich	1	4 months
Jolly	1	8 months
Goltham	1	8 weeks
Mingazzini	13 cases from literature plus 5, his own cases	From 6 weeks to 18 months
Trommer	1	1½ months
Schubert	1	6 weeks
Nonne	1	2 months
Nonne	1	4 months
Nonne	1	4 months
Nonne	1	During the secondary symptoms
Stursberg	1	During the second stage
Collins and Taylor	1	4 months

In the light of our present knowledge of serology and the cytology and chemistry of the cerebrospinal fluid we find that in cases of systemic syphilis without clinical symptoms of the central nervous system involvement abnormal changes in the fluid may be noted. For instance, in some cases a lymphocytosis of the cerebrospinal fluid, increased globulin content or a positive Wassermann reaction is observed. These abnormal phenomena prove that even in the early stages the *Spirichæte pallidæ* may invade the nervous tissue. Indeed, experimental studies of Weygandt and Jacobs demonstrate the fact that in syphilitic rabbits of two weeks' duration the central nervous system presented definite pathological alterations in the sense of meningoencephalitic process and adventitious cell formation around the blood vessels. These investigators are of the opinion that the syphilitic germ possesses a great affinity for the nervous system.

It is possible that by more careful clinical observation, associated with complete laboratory examinations, early syphilitic affection of the nervous system could be more frequently demonstrated than it had been heretofore.

Three cases of well-defined cerebral syphilis came under my direct observation in addition to several more that I saw on different services in Bellevue Hospital.

CASE I.—J. N.; Admitted to the Psychopathic Department of Bellevue Hospital May 14, 1913. Aet. 26; male; Sweden; three years in U. S. A. Sailor. Single. Family history negative. Personal History: The patient was always well and there was no history of severe diseases except in February, 1913, that is four months prior to his admission to the hospital, he contracted syphilis.

Onset of the Neuropsychic Disorder: Five weeks prior to his admission the patient began to suffer with headaches and would see black spots before his eyes. Soon he found difficulty with walking. He felt weak and somewhat drowsy. For this reason he was unable to attend to his work. Upon admission to the hospital he was rather confused, had difficulty to express himself, perseverated and appeared depressed and drowsy. On the next day the aphasia and confusion disappeared and he was able to give a good account of himself. He maintained that he was sick, complained of headaches and felt fatigued and weak.

Physically the patient was of fairly good development. There were evidence of iritis, but the pupils responded to light and accommodation. Some nystagmoid twitchings of both eyeballs were noted. Knee jerks were overactive and unequal. The gait was somewhat waddling but no definite ataxia could be demonstrated. No sensory disturbances were present. The Wassermann test was positive in the blood and fluid, and there were 280 lymphocytes per cmm. and globulin content was much increased.

CASE II.—M. G. was admitted to the psychopathic department of Bellevue Hospital, October 6, 1912. Hungarian. Aet. 20. Single. Chauffeur. Family history practically negative. Personal History: The patient was always well and of fairly good habits, except for the fact he smoked to excess.

In the early part of May, 1912, six months before neuropsychic symptoms developed, the patient contracted syphilis for which he was treated by Dr. B. Weiss, to whom I am indebted for his careful notes of the case regarding the onset of luetic infection. Three days before his admission to the hospital the patient began to complain of headaches and grew lethargic. Weakness of the right side of the body and inability to speak developed within thirty-six hours of my observation.

Upon admission to the hospital the patient was dull and drowsy, answered few questions, was dull of comprehension and manifested general sluggishness. The right side of the body was partially paralyzed, but within a day complete paralysis of that side developed with motor aphasia. Mentally the patient was dull and drowsy and occasionally he would become restless and fidgety. He was unable to speak and showed some confusion and perplexity. Physically in addition to the right sided hemiplegia with some indefinite sensory disturbances there were unequal pupils which responded to light and double optic neuritis. The right abdominal and cremasteric reflex was absent. A papular eruption al lover body, especially of the upper and lower extremities were in evidence. Wassermann test was strongly positive. There were 618 lymphocytes per cmm. and globulin was much increased.*

CASE III.—This patient came under my observation in private practice. He is a man of thirty and of fairly good habits. He always enjoyed good health; in the latter part of April, 1915, he contracted a hard chancre for which he received local treatment only. In October, 1915, (five months after the initial lesion) he suddenly felt dizzy, vomited and suffered with headaches which were so severe and intense that he could not raise his head. He was then taken to Bellevue Hospital where his Wassermann in the blood and fluid was strongly positive and cerebrospinal fluid showed a lymphocytosis and increased globulin content.

*This case was reported in detail by Dr. M. S. Gregory and the writer in *Review of Neurology and Psychiatry*, Edinburgh, May, 1913.

When he consulted me (November 18, 1915) the patient was clear mentally but complained of feeling somewhat dizzy and had heavy headaches. Physically he was fairly well nourished, and showed no evidences of visceral disease. His pupils responded sluggishly to light and there was a double optic neuritis, left more marked than right, but no other cranial nerve involvements; however, slight nystagmus was perceptible. Knee jerks were overactive, right was greater than left. The Wassermann test was 16 units. (Dr. Cyrus Field). He was later admitted to New York Neurological Institute (Dr. P. Bailey's Service) where he was treated for his condition.

The luetic etiology in all the three cases was of recent origin, varying between four and six months. In all of them a definite neurologic condition was demonstrated; in Cases I and III a meningitic affection was in the foreground. In Case II there was a meningitic involvement in addition to vascular degenerative inflammatory process. Under active treatment the patients showed a marked improvement with the exception that Case II was not very amenable to treatment because of considerable anatomical changes in the brain caused by vascular lesions. However, he made sufficient improvement enabling him to walk without assistance and he was able to speak fairly distinctly.

In the treatment of syphilis of the nervous system, two important points must be borne in mind: First is to establish the proper diagnostic classification of the case in question, and in all instances the Wassermann test and cerebrospinal fluid examination are extremely important in order to obtain a clear idea of the underlying anatomical changes. There are four large groups of cerebrospinal syphilis: (1) Meningitis, acute and chronic; (2) gumatous; (3) endarteritic; (4) mixed.

From the point of view of therapy, the first two types yield readily to anti-luetic remedies. To be sure, the question of complete restoration would depend on the intensity and degree of damage done to the nervous tissue. In prognosticating cerebral syphilis, this point must always be remembered. In the endarteritic forms the outcome is poor because the vascular changes produce certain pathological conditions in the central nervous system and in such instances, antiluetic remedies cannot replace or arrest such degenerative processes. This is also true of paresis and tabes.

The second important point to bear in mind is that in the affection of nervous system, syphilis exerts a dual action, a *local* and *general*. The former expresses itself in the nervous symptoms and the latter is purely systemic. In other words, in the treatment of such cases, our attention should be directed along these two lines, viz., to rid the system of the poison and again combat the special symptoms.

Aside from the usual hygienic, dietetic, and tonic treatment, the actual therapy of cerebral syphilis consists of three remedies: (1) Salvarsan and neosalvarsan; (2) mercury; (3) potassium iodide.

It is generally contended that salvarsan or neosalvarsan exerts a specific action on the *Spirochæta pallida* and the effect of mercury is on the inflammatory by-product as well as on the syphilitic germ. Potassium iodide aids the breaking up of connective tissue and prevents its formation. Recently the work of Jobling and Petersen show very definitely that iodides are only adjuvants in the treatment of syphilis and to sum up their views: "Iodine neutralizes the action of the agents which prevent resolution and absorption of diseased or necrotic tissue in syphilis and at the same time

lays bare to the action of real germicidal agent the infecting organism which previously had been protected by necrotic tissue. With the exposure of the infecting organism such agents as mercury and salvarsan would be more effective (quoted by an editorial writer in the *Journal of the American Medical Association*, January 22, 1916)."

In all cases where the usual contraindications are wanting salvarsan and neosalvarsan should be administered. It is always wiser to begin with a small dose in order to test the patient's constitutional tolerance. On the day following the administration of salvarsan, mercurial injections or inunctions with potassium iodide should be given. It is preferable to employ mercury salicylate injections because of rapid action and general cleanliness. The first dose should never exceed a half grain. However, the drug should be gradually increased till constitutional tolerance has been attained. In hospital work three grains a week can be used, but in private practice mercurial injections should be limited to two grains a week. In all instances the patients should be carefully watched for untoward effects. The potassium iodide should be given in increasing doses and it is remarkable how patients with cerebral syphilis can tolerate large amounts without showing constitutional symptoms. In this connection, it is important to call attention to the fact that intraspinal treatment (Swift-Ellis and Ogilvie Methods) of salvarsanized serum and mercurialized serum (Byrnes) are decidedly efficacious in the treatment of cerebral syphilis. Of course, proper cases must be selected for such treatment. In instances where acute inflammatory symptoms are intense it is better to control them by ordinary methods before instituting the intraspinal therapy.

It cannot be too strongly emphasized that the relative time duration of the actual treatment must depend upon the individual case, and one must necessarily be guided by the clinical symptoms and the Wassermann test and cerebrospinal fluid examination. In fact, the fluid examination is just as important as the Wassermann in aiding one in the therapy of syphilis.

My hearty thanks are due to Dr. M. E. Gregory for permission he has given to refer to cases I and II.

24 EAST FORTY-EIGHTH STREET

A PLAN FOR THE CARE OF THE INSURED UNDER THE PROPOSED HEALTH INSURANCE LAW.

BY A. C. BURNHAM, M.D.

NEW YORK.

UNDER the title "Health Insurance" a bill has recently been introduced in the New York State Legislature which provides medical care and invalidity benefits for every salaried employee in the State who receives less than \$100 per month. Briefly stated, the act is intended to provide New York State wage workers with medical and surgical care and a weekly cash benefit during invalidity in all cases not included under the present Workmen's Compensation Act. The insurance is to be compulsory and includes practically every vocation. The costs are to be met by contributions from the employer, the employee, and the State.

It is proposed to supply medical care, nursing, and medical supplies to the insured for a total

period of invalidity amounting to not more than twenty-six weeks during the year. In addition to this, medical care and cash benefit are provided for in maternity cases, the wives of wage earners being included under this provision. The law provides that the medical care should be adequate, but it leaves the details to the local societies, supposedly under government control.

A brief consideration of the above indicates the magnitude of the change that is contemplated in the medical care of the great mass of the population. It is claimed that no provision was made as to the character and manner of medical treatment in order that these matters might be left open for discussion and decision by the various medical societies of the State.

It is of extreme importance that the medical profession should inform itself of its position in reference to the proposed law, and that a definite plan should be formulated for the care of the insured as required by this act. It is desirable at the beginning to avoid the mistakes made under the health insurance laws of European countries, assuring adequate compensation to the physicians, competent treatment of the wage earner, with economical and satisfactory results for the State.

The writer believes that such results are possible only under a State Health Service somewhat after the plan of the Army Medical Service, or the United States Public Health Service. The basis of such a plan would be the medical center which would be the unit for a given locality. A number of these units joined together form a division which would in turn be one of the integral parts of the State Department of Health. Such a service might be shown graphically as follows:

The duties of the State headquarters and the divisional officers would be purely administrative, while the patients themselves would be under the care of the medical centers and hospitals. The existing hospitals and sanatoria are probably insufficient to care for all the wage earners who would be beneficiaries under the act and who would require institutional treatment, but in the beginning they would care for a large number of patients coming under the provision of this law, and new hospitals could be erected under State control when the need became apparent. Private hospitals stand ready to make a daily rate for hospital care as is done under the Workman's Compensation Act, and the remuneration for hospital physicians can be provided in the same manner until the State itself can undertake to provide better facilities of its own. A similar plan is followed by the army where Federal hospitals are not available.

We may now consider the basic unit of the entire system, the medical center. The medical center under the proposed plan has the entire care of the insured except when hospital treatment is necessary. It should be the aim of the medical center to prevent sickness and when it occurs to limit the disability to as short a period as is compatible with the continued health and longevity of the insured.

The following tentative plan of a medical center is presented for consideration. The medical center shall consist of the following medical officers and employees:

1. Serving on full time basis: Head physician, four assistant physicians, four visiting nurses, three clerks.

2. Serving on part time basis: Pathologist, nerve specialist, surgeon, eye, ear, nose, and throat specialist, dentist.

Headquarters shall be rented at a convenient location near the geographical center of the district served, and hours be designated for the treatment of ambulatory patients, the insured using the medical center in much the same manner as the industrial worker uses the present dispensary. In addition to this the wage earners may, when the occasion arises, notify the medical center and have medical attention furnished at his home. Usually this is accomplished with less loss of time than would be required to secure the services of a private physician.

It is estimated that this unit would care for a population of from 8,000 to 10,000 employees at a cost not to exceed \$25,000, much less than would be required if the same wage earners were cared for promiscuously by private practitioners. In order to indicate the economy of both time and money under the medical center plan, a case may be cited as handled by one of the clinics in New York City.

John Smith is sick and is told by his employer to stop work and go to the clinic for treatment. At the clinic he is seen by a clerk who searches the records for his history or if it is the first visit he takes his name and address and refers him to the examining room. Here he is seen by a nurse who takes his temperature and pulse and makes a note of the important points in his history and he is then seen by the physician. Let us suppose that he is suffering from follicular tonsillitis. The physician examines, treats, and prescribes for him in fifteen or twenty minutes and tells him to go home and go to bed, making a note to call the next day. He takes a culture of the patient's throat and gives it to the nurse, who fills out the pathological slip and sends it with the culture to the laboratory. The physician then makes a few notes on the history blank, which is given to the clerk for filing.

The next day the physician calls and finds his patient much improved but the temperature is still above 102° so that rest for several days is advisable. The culture being negative he is not concerned about the case and the third day he asks the visiting nurse to see the patient and continue treatment. On the fourth day the physician again calls upon the patient who is now nearly convalescent, but still running a little temperature. The next two days the visits are made by the nurse who reports steady progress, and at the end of a week, the temperature being normal, and the patient feeling well, he is allowed to get up and, reporting to the clinic, is told to go back to work. A complete record made by the nurse and inspected by the physician is filed by the clerk for future reference. All insurance reports are made out, and most of the clerical work is performed, without trouble to the physician.

This case, then, represents a degree of economy and efficiency of method and labor which is impossible for the private physician to attain. The physician's work consists of a maximum of professional labor and a minimum of clerical and administrative duties. He has given a case adequate professional care over a period of one week with an expenditure of not over one-third the time and exertion required of the private physician; his reports are better kept and his professional energies are preserved. It is believed that if the State Health Service is conducted along the same lines as the United States Public Health Service it will

attract the better class of physicians and give an economical service to the community.

The principal advantages of a State service may be stated as follows: (1) An economical and efficient medical service. (2) Complete records which may be easily correlated. (3) Economy in administration expenses as compared with any other method of medical care. (4) Complete control of the patient and his surroundings. (5) An elastic service which can be expanded or contracted as occasion requires.

The following are the chief disadvantages of State control: (1) Possibility of political influence and graft, which is not probable if well organized under Civil Service, and the appointments made for life. (2) The lack of sympathy and cooperation between patient and physician. It is believed that this is more imaginary than real and that patients will be glad to be treated where they receive the best care.

The salaries would range from \$3,000 to \$4,000 for the head physician down to \$2,000 for the junior physicians with an increase for length of service. Physicians would have no office, or other professional expenses, and consequently would be attracted by a career of this kind. Attending physicians who are on duty part time could be retained for about \$1,000 yearly. It is estimated that the total expenses of the medical unit as outlined in this paper would be about \$25,000, divided as follows: salaries of head physician and four assistants, \$11,000; salaries of four visiting nurses, \$4,800; salaries of three clerks, \$2,000; salaries for five specialists for part time duty, \$5,000; total salary list \$22,800. This would leave a balance of \$2,200 for rent, light, heat, cleaning, etc., which would be ample.

It is impossible to discuss here the other plans for the medical care of the insured. The plan of free choice and the contract plan are both open to serious objections and have been found wanting in countries giving then a thorough trial. The State panel, either at a per capita annual fee or at a fixed fee for each treatment, is less objectionable but has many failings, one of the chief of which is the non-standardization of treatment, and another of which is the excessive amount of clerical labor involved.

As a result of a complete survey of the entire subject the writer is of the opinion that the above system is the most economical, the most elastic, the most efficient, and in general the most satisfactory method advanced for the care of the beneficiary of compulsory health insurance.

140 WEST SEVENTY-NINTH STREET.

Trachoma in the United States.—The United States Public Health Service announces that there are thirty-three thousand cases of trachoma in Kentucky, and also that among the three hundred and twenty-three thousand Indians in our country, fully sixty-five thousand are infected. It was found, too, to be prevalent in the public schools of one of the southern cities last spring.—*National Committee for the Prevention of Blindness.*

The Goat as a Source of Milk.—The Board of Agriculture and Fisheries recommends goat-keeping to families living outside the area of retail delivery in England. Goat's milk is easily digested by infants, and less likely to contain tubercle bacilli than cow's milk. The average goat will give usually three pints of milk daily, and the unpleasant flavor can be controlled by the animal's food.—*The Lancet.*

A UNIFORM METHOD FOR THE COLLECTION OF SPINAL FLUID INTO TEST TUBES.*

BY A. LEVINSON, M.D.,
CHICAGO, ILL.

SPINAL puncture is so important a procedure and so simple in its application that every physician can do it, and most physicians have at one time or another attempted it. However, not all who make use of the spinal puncture know the fine points involved in its application. It is the man who has had a great deal of experience in this direction, who has had his successes and failures, that realizes the importance of the fine details that enter in the work. One of these is the method of collection of the spinal fluid in test tubes.

Under normal conditions the fluid is so small in amount and so uniform in nature that the whole amount to be withdrawn may be collected in a single tube, or in two tubes, and either one of these may be used for examination. Under abnormal conditions, however, the method of collection plays a great rôle, having a special bearing on the pathological findings. This is especially true in meningitis.

Very few are aware of the fact that different portions of the same fluid differ in the cellular contents, in the number of organisms contained, in the reduction index to permanganate, and even in the globulin content. Time and again I have found the cellular contents to show a difference of from 50 to 100 per cent. per cubic millimeter, between the first and last portion. Meyerhofer has shown the reduction index to permanganate to exhibit as high a difference as 1 c.c. or more from the first to the third or fourth portion. I found the same to be true in my work on the permanganate index. I also found that when a direct smear is made from the first c.c. of spinal fluid, the organism is often found more easily than in the centrifuged portions of the subsequent tubes. This is particularly true in the case of meningococcus meningitis, where the organisms are found within or just outside of the cells.

The most important reason, however, for the need of systematizing the collection of spinal fluid is the pellicle. In a forthcoming publication I expect to discuss the pellicle more fully. Here, however, I should like to point out the necessity of leaving the fluid undisturbed if a pellicle is expected to form. If the fluid is taken haphazardly and some of the fluid of the same tube is used for other purposes, the pellicle is not likely to form at all. Furthermore, a pellicle formation is accelerated when the fluid is kept in a cool place. The examination for the organism, on the other hand, is spoiled when the fluid is kept on ice, the meningococcus being killed at freezing temperature and growing luxuriantly at incubator temperature. The observance of such precautions has a great deal to do with the success of the operation. I should therefore like to present here the method I have found successful in collecting spinal fluid.

I start with four sterile and chemically clean test tubes, although in most cases three are sufficient for the complete examination. The fourth, however, comes in handy if the quantity of fluid is very large. The tubes should be labeled 1, 2, 3, 4.

Tube 1 should receive the first 2 c.c. of fluid, and this amount should be used for (1) Cytological examination; (2) Direct uncentrifuged smear for microorganisms; (3) $\frac{1}{2}$ c.c. should be used for culture; (4) 1 c.c. should be used for the permanganate test.

*From the Sarah Morris Children's Hospital, Chicago.

If not examined immediately, this test tube with its contents should be placed in the incubator.

Into the second tube should be run in from 3 to 5 c.c. of spinal fluid, depending on the amount and on the pressure. This should be put in a tube rack, and placed in the icebox for the formation of a pellicle. Care should be taken that it is not disturbed.

Into the third tube should be run 5 to 8 c.c. of fluid to be used for (1) The second portion of the permanganate test; (2) The different globulin tests (Noguchi, Ross Jones, and Nonne); (3) Lange test; (4) Wassermann test; (5) Sugar contents; and a part for centrifugation for examination of organisms if the first portion did not show it. To facilitate matters in private practice, I would suggest that the third portion should be run in into a centrifuge tube. This will in many cases give a sediment inside of one hour or even in less time, and save centrifugation. The other portion of the fluid should be taken in ordinary test tubes.

Into the fourth tube should be run in the rest of the spinal fluid desired to draw, which is from 5 to 8 c.c. on the average if the case is one of meningitis, either meningococcic or tuberculous. In the meningococcus type the withdrawal of more fluid is of value in that it makes more room for the serum to be injected, and in tuberculous meningitis it is of some therapeutic value, tending to relieve the intracranial pressure at least for some time. On the average, then, from 15 to 20 c.c. of spinal fluid should be the amount removed in cases of meningitis.

The method herewith suggested will be found to save time, in that the nurse or assistant will always know how much fluid to allow for each test tube. Its main usefulness, however, will be found in the fact that uniform results will be obtained at different examinations and by different workers.

50 NORTH MICHIGAN BOULEVARD

Medicolegal Notes.

Evidence of Negligence—Excessive Damages.—A surgeon employed to remove the adenoids of a child of seven removed them successfully, but in doing so cut her tongue. He stated to the child's father at the time that the accident had been caused by the slipping of the gag. The father testified, in an action for negligence, that the defendant pulled the instrument from the child's mouth with a sudden and vicious jerk. The defendant did not testify. It was held that the evidence was sufficient to take the question of his negligence to the jury.

The defendant contended that negligence in cases of this nature can be established only upon the testimony of competent experts. The court said that this was not a case where the sole question was upon the treatment of the diseased part, and whether it was in accordance with approved and medical standards. The jury did not have to consider whether the method of the defendant in removing the adenoids was correct or scientific, but whether the unintentional wounding of the child's tongue was caused by lack of reasonable care. This involved no question of science, or necessarily of expert knowledge. By way of illustration the court said that, if a physician undertakes to administer a medicinal poison like strychnine, or arsenic, or morphine, and by mistake gives the patient an admittedly fatal overdose, it would be illogical to hold that the question whether he exercised due care was to be determined by expert evidence alone. Nor was it any answer to say that the most eminent and most skillful practitioners are human, and that at times the most careful among them make mistakes. Nor was it sufficient to say that the child by some sudden unlooked-for movement or struggle must have caused the unexpected and unintended contact of her tongue with the instrument, notwithstanding the exercise of due care by the defendant. Her father, who

held the child on his lap, swears she did not move until the act was done, and the defendant, the only other person who could speak to the fact, declined to do so. It was therefore held that upon the whole record the issue was for the jury.

Only a slight scar was left on the tongue, without personal disfigurement, and there was a slight defect in vocalizing the letter "t." It was held that a verdict of \$1,000 rendered by the jury was excessive, and would be reduced to \$750.—*Evans v. Roberts*, Iowa Supreme Court, 154 N. W. 923.

Exemption of Charitable Hospitals from Taxation.—The Kentucky Court of Appeals holds that, under section 170 of the State Constitution, exempting institutions of purely public charity from taxation, a hospital incorporated by trustees as a charitable corporation, having no capital stock and holding property for the maintenance of a hospital for the treatment of sick and disabled persons and for medical and surgical treatment and the maintenance of poor persons not able to provide it for themselves, maintained without pecuniary profit, and having funds invested, the income of which was used solely in meeting its necessary expenses, was an "institution of purely public charity," whose invested fund was exempt from taxation.—*Mason County v. Hayswood Hospital*, Kentucky Court of Appeals, 179 S. W. 1050.

Who May Institute Proceeding for Practising without License—Chiropractors Require License.—Under the third section of the Pennsylvania act of June 3, 1911, P. L. 639, as amended by the second section of the act of July 25, 1913, P. L. 1220, imposing upon the Bureau of Medical Education and Licensure the duty of enforcing all the requirements of the act, and providing that in case of violations thereof proceedings shall be through the Attorney-General or by a special attorney, or both, at the discretion of the bureau, it is made the duty of the bureau to see that the act, as a whole, is carried into effect, and that its provisions are complied with, but there is nothing in the act which requires a member of the bureau to make the information charging a violation of the statute. The duty imposed on the bureau to institute a prosecution does not preclude any other person, either an officer of the commonwealth, county detective, or private citizen, from making the necessary information as the foundation for the prosecution.

Under the act chiropractors, though not specially named therein, are held to be within the classes contemplated by the act, and cannot practise their profession without having first obtained a license from the Bureau of Medical Education and Licensure.

The exemptions contained in the 13th section of the act indicate that in every respect, except those particularly excepted or exempted, the act was intended to cover all kinds of practice in medicine, no matter what the form might be or the agency employed.—*Commonwealth v. Byrd*, 24 Pennsylvania Dist. Rep. 1031.

Waiver of Privilege Relating to Disclosure in Insurance Policy.—The Michigan privilege statute, Comp. Laws 1897, section 10,181, which prohibits disclosure by a physician of information imparted to him in his professional capacity by a patient, was amended by Pub. Acts 1909, No. 234, providing that after the decease of such patient, in a contest upon the question of admitting his will to probate, his heirs at law shall be deemed to be his personal representatives to waive the privilege. An insurance policy issued by a fraternal benefit organization provided that the insured waived her privilege relating to the disclosure by attending physicians of information obtained while acting as such. It was held that the waiver was inoperative to render a physician's testimony admissible, since the Act of 1909 creates the only exception to the prohibition against physicians' testimony.—*Gilchrist v. Mystic Workers of the World*, Michigan Supreme Court, 154 N. W. 575.

Harrison Opium Act—Hospital Employees.—The Attorney-General for the State of Pennsylvania is of the opinion that the exemption in section 1 of the Harrison Opium Act of the "officers of State governments or of counties and municipalities lawfully engaged in making purchases of such drugs for State, county, or municipal hospitals or prisons," does not include the superintendent and other persons attached to State hospitals, they not being officers of the State government. The proper officers of the State government, being exempted by the act, may make such purchases for State institutions.—24 Pa. Dist. Rep. 248.

THE TREATMENT OF VARICOSE LEG ULCERS.

IN most surgical divisions of the out-patient departments of our hospitals varicose leg ulcers are considered as almost if not quite an unmitigated nuisance. The treatment of these cases is usually handed over to the junior members of the staff, who are generally allowed or even encouraged to pursue their own inclinations as to methods of treatment unhampered, or with few words of advice from the senior surgeons. Unfortunately, most of them were taught that at some stage in the healing of an ulcer salves should be applied. Furthermore, the idea that salve is "soothing" to the ulcer is firmly implanted in the minds of the laity; hence both patient and doctor have felt that the right thing was being done when boric, zinc oxide, or some other ointment or Lassar's paste was applied to the ulcer and the treatment completed by the application of one or two compresses, held in place by a gauze bandage. This process has often been repeated every two or three days for weeks, months, sometimes even for years, and still for some mysterious reason the ulcer has not been cured. Such patients often migrate from clinic to clinic until finally they may be fortunate enough to fall into the hands of someone who appreciates the principles involved and carries out treatment on a rational basis.

When a varicose ulcer is first seen at the clinic usually two things are indicated: (1) the ulcer must be cleaned up and stimulated either by curetting, or by the application of a strong solution of silver nitrate, or some other such agent, and (2) the chronic passive congestion must be eliminated as far as possible by the application of a firm supporting bandage. If there is any syphilitic taint, antisyphilitic treatment must be instituted, while steps must also often be taken to raise the general physical condition. Further local treatment will consist in stimulation of the ulcer, when necessary, the protection of the granulations, and, most important of all, proper support for the tissues, usually by a carefully and properly applied muslin bandage.

Some of these points are well brought out and elaborated by P. G. Skillern, Jr., in the *Annals of Surgery* for February, 1916. In this article he emphasizes three cardinal principles in the

treatment of varicose leg ulcers, namely, the necessity for (1) protection, (2) drainage, and (3) support. In obtaining this last requisite he points out the efficacy of Unna's zinc-oxide-gelatin paste dressing in certain cases. His conclusions are mainly as follows: (1) The rationale of treating varicose leg ulcers is to establish a tendency to heal by combating the pathological hindrances to healing. (2) These hindrances to healing are due to chronic venous congestion. (3) The rational treatment of varicose leg ulcers depends upon the recognition and application of the principles of protection of the regenerating epithelial edge, drainage of the discharge from the ulcer, and support of the venous channels from without, thus neutralizing the baneful effects of chronic venous congestion. (4) The agents employed in the rational treatment of varicose leg ulcers may be summarized by terming the method the rubber tissue-dry gauze-muslin bandage method. In selected cases the calomel-adhesive plaster strapping method cures rapidly and efficiently; while for routine treatment of the average case Unna's zinc oxide-gelatin paste stocking serves as an efficient support. (5) The tendency to healing has been established when the base of the ulcer is covered with healthy, red, vigorous granulations, and when the epithelial edge becomes broader and assumes a pale, bluish-white tint. (6) If in a case of multiple varicose leg ulcers the smallest ulcers become completely covered with epithelium under the influence of treatment, it has thereby been proven that a tendency to healing has been established, and that in time the larger ulcers will heal, if not too large, excessively fibrosed, or adherent to bone. (7) Healing of the ulcers having been brought about, it remains to prevent recurrences. Recurrences may be prevented mechanically by the use of a silk-elastic stocking or by a Randolph bandage; and barking of the shin should be insured against by a shin-guard or wool padding of the part of the stocking that covers the shin. If an operation for excision of varicose veins is indicated it should be performed after healing of the ulcer has taken place; otherwise the operative wound might become infected from the ulcer and septic thrombophlebitis, with all the attendant dangers of embolism, might then ensue. (8) The success of this treatment proves the fallacy as well as the futility of expecting cure from the application of medicaments, while overlooking the fundamental pathological etiology of the ulcer.

EXPERIMENTAL PRODUCTION OF MUMPS.

EPIDEMIC parotitis has attracted comparatively little attention from the research workers. A few have endeavored to produce the diseases by the inoculation of animals with organisms isolated from the saliva of patients or with material isolated from the affected gland. Others have made inoculations with a filtrate of the saliva and have obtained suggestive results. The fact that intratesticular inoculation has been of such aid in bacteriological investigations and that the testicle is so frequently involved in mumps stimulated Wollstein to attempt this method of studying the etiology of the disease. In

a recent article (*Jour. Exper. Med.*, 1916, xxiii, 353) she reports the results of a large amount of experimental work which yielded quite successful results. Rabbits and monkeys gave poor results, and she used cats almost exclusively for her experiments.

The material used was obtained by washing the mouth with sterile salt solution after massage of the affected parotid gland. This was then passed through a Berkefeld filter and found to be sterile. Injection of one cubic centimeter of this material was then made directly into the substance of the parotid or the testicle. After the preliminary mechanical reaction, which subsided within twenty-four hours, there was a quiescent period of from six to seven days, after which there appeared a swelling and tenderness of the gland so inoculated. Coincident with this there was a marked leucocytosis with generally a polynucleosis. There was also a temperature rise of between 1 and 1.5 degrees. The initial polynucleosis was usually followed by a lymphocytosis. The parotid changes were less marked than those in the testicle, which latter persisted for from eight to twelve days and in some instances were followed by atrophy of the gland. The author was able also to transmit the disease from cat to cat by the injection of material obtained from the affected gland. The work was controlled by the injection of filtrates from the saliva of healthy individuals and of material prepared from the parotids and testicles of uninoculated cats, all of which produced only temporary rises of temperature and swelling in the gland. A mixture of the infectious material with the serum of cats which had recovered from an inoculation produced a distinctly less active reaction than that developing in control animals. Reinoculation of animals which had recovered also produced but very little effect.

This work does not, of course, solve the problem of mumps. It is apparently successful in the reproduction of the experimental disease, however, and shows quite effectively that the infectious agent is a filterable virus. Attempts to grow the virus by the method of Noguchi are not reported upon. The serum protection experiments are especially interesting, since they suggest that the work already done in the use of immune serum in the prevention of scarlet fever and measles can possibly be extended to mumps.

TOXICITY OF EMETINE.

LITTLE is known concerning the toxicity of emetine, and little information can be gleaned from medical literature regarding the subject. Experiments on animals do not reveal to a satisfactory extent the effect on man, and its effects on man cannot be gauged accurately enough to render such kind of evidence of a very convincing character. Dr. Andrew Balfour, writing in the *Journal of the Royal Army Medical Corps* for January, 1916, points out that treatment by emetine is comparatively recent, dating only from 1912. The doses employed are usually well below those required to produce toxic symptoms; and again, there is not yet sufficient evidence to show whether certain symptoms, noted after the treatment of dysentery with emetine, are

due to the disease or the remedy. With regard to its effects on human beings, Zept carried out experiments in two directions: (1) Giving small doses of emetine per ounce to phthisical patients, and (2) giving suppositories of emetine to lunatics. His main conclusions were that emetine when applied locally is irritating to both ends of the digestive tract; that it causes loss of appetite, stomach troubles, and headache; that it has an action on the upper respiratory passage and exerts a depressing effect on the central nervous system. He did not study the action on the heart. Cushing states that in man vomiting has followed the hypodermic injection of 4 grains of emetine, but 1 grain administered in this way has no such effect.

Intensive treatment by emetine is reported to have brought about intense salivation in one case. This may have been an instance of special idiosyncrasy to the drug. A large dose of ipecacuanha wine has produced death. Balfour, in concluding his review, says that medical officers treating cases of amebic dysentery with emetine will do well to remember: (1) That it is a very costly drug. (2) That if it is going to do good its beneficial action is generally quickly apparent. (3) That it is useless, unwise, and wasteful to subject patients to repeated or long-continued courses of the drug. Very little is known of the possible cumulative action of emetine. There may be none, but in any case two short courses of the drug in appropriate doses will usually suffice to cure a case of amebic dysentery. This would necessitate a primary administration of in all from 10 to 15 grains, and accords with the experience of Low in his recent article on the treatment of amebic dysentery. (4) That emetine may itself produce and keep up a certain degree of diarrhea, and that it is important to distinguish this drug-produced diarrhea from that caused by intestinal disease.

THE FURRED TONGUE FETISH.

OF course the exact pathology of coated tongue has not yet been definitely determined, although we are aware that it is a proliferation of the epithelial layer. It has long been held that this phenomenon indicates some disturbance of the digestive apparatus. We call to mind the respected (and feared) spinster in our community a good many years ago who had her own opinion of doctors. Urged to consult one of this fraternity when a little indisposed she would repel the suggestion with scorn. "All they do," she would say, "is to say, 'Let's see your tongue. How's the bowels? Two dollars, please.'" We have met with clinicians of the old school who could make a pretty accurate diagnosis by looking at the tongue and we have also had the pleasure of accompanying a physician on his hospital rounds who could diagnose a case of pneumonia in a child he had never seen before when he was yet ten feet away from the bed. And what is more, he could tell which side it was on and even designate the lobe affected in some cases. Most of us, however, are not gifted with this diagnostic acumen; we must go into all the signs, objective and subjective, and even then we do not come right out and make an irrevocable statement—we usually leave a loophole or two.

Dr. Goodhart in the *Lancet* for September 25 calls attention to coated tongue which is totally dissociated with gastrointestinal disturbance. This is the furred tongue of the neurotic, especially the hypochondriacal type. Goodhart reports two cases of it. It is, of course, well known that the type of person who develops a neurosis seems to be able to develop almost any symptom there is in the realm of medicine and the coated tongue would naturally be a frequent selection, so to speak, this condition being extremely familiar to the laity. Just what causes the actual physical appearance of a "coat" on the tongue in these cases is, of course, not easily explained, although the best way to approach it would seem to be along the line of conditioned reflexes. The treatment would naturally be the treatment of the underlying neurosis.

Facts which seem to support the theory of a nervous origin of the coated tongue in cases otherwise unaccounted for are the development of this symptom soon after a fracture of the base of the skull and the well-known tendency of the hemiplegic to develop a coated tongue. So when we next run across this symptom, especially in a patient who comes to us chiefly on that account, let us not turn to a mental pigeon-hole and bring out together the time-honored trinity—coated tongue, disordered stomach, liver trouble—but approach the subject with an open mind.

STEALING THE SUNSHINE.

MUCH attention has been given of late years to the hygienic conditions which surround workers, especially with regard to heat and ventilation. Little study comparatively has been given to lighting, it being taken for granted that if the worker was able to see what he was doing it was sufficient. The reason for this indifference is not far to seek. The occupant of a room which is too cold or too hot soon complains about it; the foreman, the manager, and the owner soon notice it if they are obliged to spend any time in the room and these see that it is corrected. The atmosphere of a room which is insufficiently ventilated immediately warns a visitor that something is wrong. But the supervisors who are not obliged themselves to use the light so constantly and whose desks are usually the most favorably situated in the room do not often appreciate the eyestrain under which the subordinates labor; in fact, the latter only rarely appreciate it themselves. The first report of the Departmental Committee on Lighting in Factories and Workshops has been recently published in London, and shows some startling facts. For instance, in testing the strength of the illumination in a workshop on a well-lighted top floor, they found it was only 2 to 10 per cent. of the direct sunshine. In other words, workers in what would ordinarily be considered favorable conditions were losing 90 to 98 per cent. of the light. No wonder that eyestrain and headaches are common among indoor workers. It has been found that as a matter of fact spectacles are much more commonly in use among them than among outdoor workers. Much, of course, can be done by improvements in the system of lighting and in one case the committee found on investigating a workshop where a better system of lighting had been installed that the production had increased 10 per cent.

News of the Week.

New York City Death Rate.—The health of New York City during the week ending April 8 was considerably better than during the corresponding week of last year, the respective rates being 15.63 and 18.51 per 1,000 of population. This decrease in the death rate is equivalent to a saving of 309 lives. The only disease which showed an increased mortality, in the comparison of the two periods, was cancer, the number of deaths reported from this cause during the week being 113, as compared with 92 during the same week of 1915. The death rate for the first fifteen weeks of 1916 was 15.64, as compared with 15.50 for the corresponding period of last year. Considering the unfavorable climatic conditions prevailing this spring, and the rather severe outbreak of influenza which took place last January, the Health Department considers that this showing is very good.

Chicago Death Rate.—During the month of March, 1916, there were reported in Chicago a total of 3,440 deaths, giving a death rate of 16.3 per 1,000, as compared with a total of 3,214 deaths and a rate of 16.2 for February, 1916, and a total of 3,565 and a rate of 17.2 for March, 1915. Twenty-five deaths were due to typhoid fever, as compared with 12 in each of the other months, and 25 to scarlet fever, as compared with 12 in February, 1916, and seven in March, 1915. Tuberculosis caused 352 deaths during March, 1916, and 411 in March, 1915, and there was a decrease, also, in the comparison of the two months, in deaths due to cancer, heart disease, and nephritis.

Huddleston Memorial.—The friends of the late Dr. John H. Huddleston, desiring to establish a fitting memorial to him, have determined upon the establishment of a modest organization to develop the work of caring for what are known as "cardiac children," that is, children of the poor who are found to be suffering from constitutionally weak or diseased hearts, but who, under proper treatment, can be developed to comparative strength and to usefulness in many industries. In the years just preceding his death Dr. Huddleston was intensely interested in such cases, and had already made a beginning in the organized treatment of them. He felt strongly that this field, little cultivated up to date, afforded a wonderful opportunity for preventing many such defective children from falling, not only into permanent disease and disability, but into such physical and nervous weakness as to lead them readily into decadence and crime. After canvassing the whole question, therefore, a committee having the matter in hand has reached the conclusion that the development of such an organization will form the highest possible tribute to Dr. Huddleston's memory. The aim is to secure a fund of \$40,000, with which a definite and satisfactory start can be made in the Gouverneur district, to which Dr. Huddleston had devoted much of his time, and, perhaps, in two or three other districts. The work will be carried on under the general supervision of an executive committee, consisting of Dr. L. Emmett Holt, chairman; Dr. Lewis A. Connor, Dr. Haven Emerson, Dr. Philip Van Ingen, Dr. A. S. Knight, and Dr. H. B. Wilcox, who will serve without compensation. It is believed that this plan, if generously supported, will serve to perpetuate, in practical and admirable form, a memorial worthy of the loving kindness and noble character of Dr. Huddleston.

A Conference on the Training of Medical Missionaries was held April 5 and 6, 1916, under the presidency of W. Douglas Mackenzie, D.D. The conference was well attended, and an interesting program was provided. Several papers were read on medical missionary work. Dr. Alden R. Hoover, missionary of the American Board in Turkey, on leave of absence from Red Cross work in Constantinople, read a paper on the different types of medical service called for in the foreign field and the personal qualifications essential to success. Prof. Horace D. Arnold, M.D., dean of the Graduate School of Medicine in Harvard University, dealt with the preparation of the medical missionary for his task. Dr. Belle Allen, missionary of the Woman's Foreign Missionary Society of the Methodist Episcopal Church in Baroda, India, devoted her attention to a consideration of the preparation of women for medical mission service and how it should be differentiated, if at all, from that of men. Dr. Paul W. Harrison, missionary in Arabia of the Board of Foreign Missions of the Reformed Church in America, gave a paper, in which he discussed the preparation which medical missionaries should have in addition to their regular medical studies. The question of medical preparation for missionary work was debated from all angles, and it was decided to recommend that a high school course of four years and a college course of at least two years be taken before commencing medical studies. It was further urged that, when possible, it would be well to take a full course of four years in college. So far as medical training is concerned, it was recommended that a course of four years in a medical school of Class A should be taken, the regular curriculum to be followed, and no attempt made to specialize except through optional or elective courses. After a degree in medicine has been obtained, at least one year as interne in a good hospital should be required. It was also strongly recommended that one year of post-graduate study should be taken in subjects which are important for medical missionary work. Among these subjects emphasis was laid upon the need for a medical missionary to take courses in preventive medicine, hygiene, and sanitation. It was also recommended that, in view of the scope of the medical work of women physicians in the Orient, women medical missionaries should be specially trained in obstetrics, and in the diseases of women and children. The acquirement of such knowledge predicates supplementary study and hospital experiences in these branches. It was further recommended that opportunities should be afforded medical missionaries for prosecuting research work.

The Hay Bill Condemned.—Our attention is called to an error in the news item with this heading in the issue of April 1. It was there stated that at a recent meeting of the County Medical Society a resolution was passed to the effect that there should be in the United States Army in time of peace one surgeon to each 1,000 enlisted men; this should have read *seven* surgeons to each 1,000 enlisted men. The resolution did not condemn the Hay bill *in toto*, but only that section of it abolishing the Medical Reserve Corps of the United States Army.

In Honor of Dr. Welch.—A supper will be given by the Harvey Society in honor of Dr. William H. Welch following his lecture upon medical education before the society on April 29. The supper will be given in Sherry's ballroom.

Preparedness Meeting.—Major-General Leonard Wood, himself a physician, spoke on the subject of preparedness to more than 300 students and officers of the College of Physicians and Surgeons, New York, on April 12.

New York Geriatric Society.—A meeting of the New York Geriatric Society was held at the Sherman Square Hotel, New York, on April 19. The subject for discussion was "Senile Neuroses and Psychoses."

Street Accidents.—The Department of Health of the City of New York calls attention to the fact that in the city last year street accidents caused nearly twice as many deaths as did typhoid fever, and comments on the little attention paid by health officers generally to these as a cause of injury and death. Recent statistics prepared by the Police Department put the total of street accidents in the city during 1915 at 22,540, of which 659 were fatal. Of those killed, 510 were males and 149 females; 106 were children under 6 years of age, and 184 were between the ages of 6 and 16. The statistics show that the principal causes, in the order of importance, were as follows: Passenger automobiles, 4,866; electric street cars, 3,026; falls, due to causes other than vehicular, 3,005; horse-drawn vehicles, trucks, or wagons, 2,441; collisions of all kinds, 2,428. The other causes were comparatively insignificant.

Personals.—Dr. ANTHONY BASSLER has been appointed consulting gastroenterologist to Christ's Hospital, Jersey City, N. J.

Dr. CHARLES A. POWERS of Denver, Col., sailed for Paris on April 8 to serve for three months in the American Ambulance in that city.

Dr. FLOYD M. CRANDALL of New York has been appointed secretary of the Medical Society of the State of New York to fill the vacancy caused by the death of Dr. Wisner R. Townsend.

The Saratoga Reservation.—The New York Legislature has passed the bill placing the control and development of Saratoga Springs in charge of the Conservation Commission of the State. The chairman of the commission will, we trust, appoint a business man of proved executive ability as his deputy to take charge of the development of the Springs.

Obituary Notes.—Dr. OSCAR J. STAFFORD of Port Chester, N. Y., a graduate of the Medical Department of the University of Buffalo, in 1888, and physician to the United Hospital of Port Chester, died suddenly, while attending a patient near his home, on April 12, aged 58 years.

Dr. JOHN W. CULVER of Jersey City, N. J., a graduate of the New York University Medical College in 1895, died at his home, on April 12, after an illness of several weeks.

Dr. LOUIS HATTON of Camden, N. J., a graduate of the Philadelphia University of Medicine and Surgery in 1864, died at his home, on March 27, aged 81 years.

Dr. CHARLES CLAXTON of Philadelphia, a graduate of the Medical Department of the University of Pennsylvania in 1882, died at his home, on April 4, aged 57 years.

Dr. SMITH COOPER of Wilmington, Del., a graduate of the Medical Department of the University of Pennsylvania in 1876, and a member of the American Medical Association, the Delaware State Medical Society, and the New Castle County Medical Society, died at his home, on April 6, after a short illness, aged 64 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

RETRENCHMENT—BOARD OF CONTROL—LOCAL GOVERNMENT AND EDUCATION BOARDS—NATIONAL INSURANCE—REPORT OF ROYAL COMMITTEE.

LONDON, March 24, 1916.

THE final report of the Retrenchment Committee has been issued and is obtaining consideration by the press. Its scope did not include expenses of the army, navy, or munition services, and even in civil departments it was advised to avoid questions already decided by parliament as at the present time there is no opportunity for legislation which may involve controversy. The first thing to strike the reader of the report is the enormous, one may say unprecedented, increase of expenditure—nearly 200 per cent.—to be exact, from £32,000,000 in 1895 up to £90,000,000. This is mostly due to new grants and the parliamentary legislation which has involved them, as *e.g.* old age pensions which reached £13,500,000, national insurance and labor exchanges £9,500,000, and education £12,000,000. Such measures as have been taken to promote a reduction of expenditure have not been effectual. There was an increase of £205,000 in the cost of the civil service and revenue for 1915-16, but the estimates for this year, excluding items connected with the war, show a decrease anticipated to be over £3,000,000. Looking round for some expense to curtail, the committee pounces on the reports of certifying surgeons on accidents which cost £12,500 per annum; and it supports the proposal of the Factories Committee and obtains legislation for their abolition. The board of control consists of ten commissioners and the committee recommends a reduction of numbers as well as of salaries, commencing by not filling up early vacancies. A reduction in the contributions toward the cost of institutional treatment is also advised, and a definite limit of cost of maintainance in all cases.

The vote toward the Local Government Board has risen from £221,000 in 1905-06 to £362,000, mainly through the increased attention paid to medical, sanitary, and housing problems, and the committee recommends a special inquiry into the administrative staff. Further, it falls on the medical fees for notification of infectious diseases, which have steadily risen of late years and will probably rise higher as measles and German measles are added by a recent order to the diseases to be notified. It says as doctors have now become familiar with notification, the 2s. 6d. fees might be reduced to 1s. Would they venture on a parallel proposal to the legal profession?

The medical work of the Education Board and the Local Government Board overlaps as regards the arrangements for the health of mothers and young children (under school age)—thus two government departments are dealing with one problem. This should not be, and many are saying that the control of all such institutions had better be handed over to the Local Government Board to administer in connection with its public health work and in co-operation with its local authorities. Such a plan has succeeded in Scotland, but perhaps definite amalgamation would be better still.

With regard to national insurance, the committee does not think centralization of the whole service practicable, but that it should be possible to devise

a scheme safeguarding national sentiments without retaining all the 21 commissioners with salaries amounting together to £24,600 per annum. The cost of the central administration per thousand insured persons seems to be in England, £28; Scotland, £36 14s.; Wales, £51; Ireland, £59 14s. These differences may well attract the attention of economists, for the committee professes to be unaware of conditions which would account for them, but expresses the opinion that much could be done to reduce the expense of the Act and to increase the sums available for benefit by simplifying its provisions. Something has been done in this way by departmental action, but much more might be accomplished and great savings achieved by a brief act of parliament increasing the powers of departments.

The Report of the Royal Commission on Venereal Diseases is issued this month. Eighty-five witnesses were examined, to whom 22,296 questions were put. The report opens with notice of previous action by the State, particularly with regard to the army and navy, the Contagious Diseases Acts and the opposition to them, which led to the Royal Commission and later to the parliamentary proceedings and the intense public controversies which followed.

FRATERNITAS MEDICORUM; A REPORT AND A DISCUSSION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR—In the issue of the MEDICAL RECORD for July 31, 1915, an "Appeal to the Men and Women Engaged in Medical Practice and the Advancement of Medical Science" was published, asking them to join the organization of the Medical Brotherhood for the Furtherance of International Morality. It was signed by about one hundred and fifty members of high standing in the profession of this country, many of whom enjoy an international reputation. Soon after its publication, we began sending out the Appeal and an enrollment card to members of the medical profession. We wish now to give an account of the results thus far attained, and to discuss the nature of this venture and its merits.

Report.—To this date over thirteen thousand American physicians have enrolled as members of the Medical Brotherhood, the greatest part of whom are either members of some medical societies of good standing or of societies which cultivate medical sciences. The Appeal was also sent to some leading members of the profession of other neutral countries. Here again we obtained very encouraging results. We received, and continue to receive, requests from members of the medical profession of these countries to be enrolled as members of the Brotherhood of our country. Among our correspondents are such well-known men as Theodor Kocher, Einthoven, Thalma, Rovsing, Thunberg, Von Monakow, Zwaardemaker, de Quervain, Jaquet, Marsden and others of similar standing. The Appeal was published in some of the medical and scientific journals of these countries, and we have the encouraging information that organizations similar to ours were started there. *We did not approach members of the profession in any of the belligerent countries;* nevertheless, we received requests to be enrolled from medical men in Finland (Russia) who probably read the Appeal in Swedish medical journals.

The thirteen thousand members of the medical profession of this country who have enrolled as

members of the Brotherhood represent about 15 per cent. of the number of physicians to whom the Appeal was sent. We have, therefore, good reasons to consider henceforth the *Fraternitas Medicorum* as an established organization.

Analysis of Objections.—While it is idle to speculate as to the real attitude of those who did not respond to the Appeal, certain instructive facts, capable of shedding some light upon this question, may be, nevertheless, learned from an analysis of part of the correspondence we have had. We shall not include in the discussion the numerous letters in which the writers unreservedly and enthusiastically approve our movement. But we have to mention that among the enrolled members are some who originally looked upon the enterprise with misgivings. We shall mention further the instructive fact that a number of physicians asked for enrollment cards months after the Appeal was sent to them, stating frankly that they threw away the Appeal without even having read it, because they were bothered with too many war and peace circulars.

However, we received about twenty-seven letters, the contents of which were unmistakably adverse to our movement. Nine of these communications were anonymous; they contained coarse, grossly offensive remarks, assuming that the Medical Brotherhood was a part of an organized German propaganda, and insinuating further that the expenses were met by the German Kaiser.

Among those who signed the adverse letters are several from men who are of high standing in the profession, and are personally known to us. Several of our correspondents, some of whom were during the present war for short periods in France, stated that there is not a neutral fiber in them; their only goal is to crush the Germans; although some of these writers seem to be willing to join the Brotherhood after the crushing process has been accomplished. It is an instructive fact that in this group were two with "100 per cent. German blood" in them. Two German physicians, on the other hand, did not wish to join because they "feel too strongly pro-German to be neutral." Two physicians objected to the idea that physicians have a higher claim to international morality than other people. Several of our correspondents said that they either could not see the object of the movement or, as one expressed it, he could not see where "the uplift comes in"; or, on the contrary, that the aim of the Brotherhood is too Utopian for them. Finally, several writers approved the idea in general, but thought that the organization of a Medical Brotherhood should be postponed until after the war.

The objections to the organization of the Medical Brotherhood, so far as could be ascertained from this small number of adverse manifestations, may be summarized as follows: (1) That it is a part of a German propaganda, or, at least (2) a veiled pro-German movement; that (3) it is meant to be a neutral body which, therefore, ought not to be supported because the paramount duties of American physicians ought to be to crush the Teutonic Allies; that (4) physicians have no higher claim than other people to international morality; that (5) there is no object (no uplift) in this organization; that (6), on the contrary, the object is too Utopian, and finally, (7) that the movement is premature.

Financial Resources.—Small as the number of our critics are, their adverse points of view merit public discussion. In so doing we shall deal in the

first place with the most objectionable interpretation given to the aims of the Medical Brotherhood, namely, that it is part of a pro-Teutonic propaganda and that it is financially supported by the German government. In the Appeal, as well as in a letter published in the *Journal of the American Medical Association* (Vol. 65, p. 971), it was expressly stated that the Brotherhood is neither a pro-Teutonic nor a pro-Allies movement. Such assurances probably do not reach the type of men who are capable of writing anonymous letters. But we owe it to the medical profession at large to make the following statement regarding the financial resources of the Medical Brotherhood, which is as follows: Private contributions, to the amount of \$622, were made, in smaller and larger sums, by some of the enrolled members. The main financial support comes, however, from the Carnegie Endowment for International Peace. The Executive Committee of this body granted us a liberal fund for the purpose of developing our organization. The Executive Committee is made up of such prominent Americans as President Butler, President Pritchett, Elihu Root, and others of similar high standing. It is quite safe to say that no individual with normal judgment could think for a moment that these foremost American citizens would consent to support a pro-Teutonic organization. But ought such a question to have been raised at all by any fair-minded member of the profession in the face of the standing of the members of the committee which signed the Appeal? Would, for instance, the Surgeon Generals of the Army, of the Navy, and of the Public Health Service consent to be honorary presidents if the Medical Brotherhood had some ulterior, pro-Teutonic or other un-American tendencies?

General Discussion.—As to the other criticisms, they can be best met, we believe, by discussing the fundamental considerations underlying this movement. The term "brotherhood," it is true, recalls to mind a state in which all men shall treat one another like brothers—like good brothers. This is a visionary ideal which probably will never be attained. The specter of the unattainable drives practical men away from such ideals. But it should be remembered that even the unattainable ideal may be of great educational value, if utilized merely to indicate the *direction* which our practical activities ought to take. However, the Medical Brotherhood directs the appeal only to the medical fraternity, and does not intend to deal with unattainable objects. The medical profession has a training which is scientific in character and method, and which has, in modern times, among its precepts the following maxims: (1) The development of a new view must be started on the basis of an assured fact and not from mere desire or by the impulse of an untamed phantasy; (2) not to be afraid to assume, or to work for, something which has not received the approval of that great authority, the practically wise man; (3) not to work for the demonstration of the correctness of the new assumption, or for the realization of the new aim, in the manner of the practical man; that is, by violent activities and in the expectation of attaining completely the desired end in a month or a year (perhaps to lose it again in a shorter time), but to work patiently, trying to attain the end, or even only small parts of it, by steps which may appear to be very small but which offer the greatest chance for permanency; (4) not to be discouraged by some failures; and, finally, (5) by caring more for progress in the right direction, than for attainment of the goal.

Now, we started on the development of our organization on the basis of the following indisputable facts. The ethical relations between separate nations are thousands of years behind the state of morals governing the relations of individuals of the same nation. International morality progresses at best in waves, positive and negative, making perhaps three steps forward and two and sometimes four or five steps backward. However, during the normal state of the world's affairs, ethical men of all countries are ready to be guided by the two great moral principles: patriotism and humanity. The present world-wide catastrophe has demonstrated, however, that even the most idealistic citizen is incapable, and, in fact, is not in a position to serve both ethical principles at the same time, while his country, right or wrong, is at war with another country. Physicians, however, are in an exceptional position; they are permitted and even required to observe both ethical demands even during war. In war the physician's services to his country are as necessary, as great as that of the warrior, but he is in the fortunate position to be able to treat his compatriot and his country's foe alike. That standard of morality is upheld not only by the medical profession itself, but is practically demanded by the regulations agreed upon by the various international conventions, regulations which have been rarely broken even in the present most brutal war. Even in the present state of frightful confusion of judgment, practically no sane individual exists who would not consider this standard of morality desirable to obtain in all domains of human endeavor—if it were attainable. These are safe facts. Now the Medical Brotherhood was organized primarily to bring these instructive facts to the consciousness of the members of the medical profession, to tell them of their ethically privileged status. This message is not sent to non-medical men; neither do we mean to say to the non-medical man that we physicians are holier than thou. We wish only to convey to physicians the message that their profession permits them to remain at all times simultaneously patriotic and humane, and that they should train their character properly so that they could be fit to exercise this high privilege. The nearest and simplest end to be gained from such information is the consciousness of a sense of higher duties which comes from the knowledge of one's higher moral dignity.

There is no doubt that the medical profession is a noble calling. Do medical men represent a noble class? They ought to. There are two good reasons for such an expectation. "A medical man whose ethical standard is not above that of the average man is morally below him." His activities are of a most serious nature; they concern life; and, furthermore, they can not, as in other callings, be controlled by anybody or anything else but the physician's own conscience; that conscience therefore must be of a higher type. Then the physician has constantly to deal with suffering, that of the patient and of those to whom the patient is dear; sympathy, therefore, ought to be an integral part of the make-up of the desirable physician. It is true that the medical calling is at the same time the physician's business by which he makes his livelihood; it is therefore often afflicted with many of the moral shortcomings which frequently go with money-making occupations. The Medical Brotherhood, however, does not deal, and does not have to deal, with this side of the physician's life. It deals with the physician in his relation to his coun-

try, when he acts and has to act as a patriot; or when other countries are at war with one another, when the physician of neutral countries has to act as a humanitarian. Here every physician can afford to exercise his noble profession in a noble spirit. It is that for which the Medical Brotherhood appeals to all physicians of our country. That alone seems to us to be an object worth while looking for. It may appear to some "practical men" as too small or even "too foolish" an object to waste their attention on. Let these wise men stay out of the Medical Brotherhood; it may be of benefit to the aims of the movement. Many of the practical men have always been stumbling blocks in the path of progress. The marvelous progress of medicine in this country during the last three decades was attained against the good will of this influential class of medical men.

The fact that within only about eight months and without agitation and publicity, thirteen thousand members of the medical profession of the United States alone should have joined the Medical Brotherhood shows that we struck the right chord. This group of medical men and women, the vast majority of whom surely have more or less idealism, represent about 10 per cent. of the medical profession of this country. Moreover, there can be no doubt that the Appeal issued by the committee exerted a morally favorable influence upon many members of the profession who did not formerly join the Medical Brotherhood; and there is great probability that a good many will join it when the war approaches its end.

In this connection we may call attention to the most encouraging fact that the medical journals of our country act in a most exemplary manner with relation to the war. None of the journals, at least none known to us, has indulged in offensive discussions of the various belligerent nations or made disparaging comments on the behavior of the medical members of these nations. The subject of the present war has been handled by the medical journals with rare good sense and tact. In a general way, the same may be claimed for the utterances of the members of the medical profession when made in lay gatherings or publications, although here the unavoidable small fraction of exceptions has not been lacking. The Medical Brotherhood has had occasion to remonstrate in two instances, in one with complete and in the other with partial success.

From the point of view of the scientific investigator, who is not afraid of Utopian ideals which may give him the direction for his work, but who works for his goal by small and practicable steps, we may claim for the movement of the Medical Brotherhood that it has a definite object, "an uplift," that it is not Utopian in its direction, that it was undertaken at the right time—when the medical mind was in a state of fermentation—in *statu nascendi*, and, best of all, that the movement has already attained a gratifying success: it has aroused the moral, humane spirit in a great many members of the profession in this country as well as in other neutral countries.

We have no quarrel with those of our colleagues who do not wish to join the Brotherhood, because, as they say, they can not remain neutral in this war. No matter with which party one sides, and what his wishes may be, we do not question the moral nature of his motives. But we wish to make the following two remarks: First, the Medical Brotherhood does not aim for mere neutrality. A neutral occupies, with reference to war, the same moral level as the

belligerents, with the mere difference, that he is not in it, or not yet in it. The Medical Brotherhood wishes to occupy a position above this level. War represents a very backward place in the development of human ethics. The various belligerent nations are simply products of the same moral phase, the same developmental period. The medical profession is fortunate to be able to occupy an advanced ethical position. Its members should be aware of it, and should adhere to it. Secondly, the Medical Brotherhood is concerned only with the medical part of its members. As private individuals the members are at liberty to sympathize chiefly or exclusively with one side or the other of the warring parties. What we expect of members of the Medical Brotherhood is that they should commit no public act which is not in harmony with the advanced moral standing of the medical profession. One who does not feel that he can bind himself to this simple obligation, or one who does not believe, or does not want to assume, that the medical profession occupies an advanced moral position, should, of course, not join the Medical Brotherhood. This organization must consist of medical men and women who believe in the advanced ethical position of the medical profession and are willing to live up to this belief. It is as certain as day that only good and no harm can come from such a belief.

We shall not risk the presentation of a list of the problems which we may be called upon to try to solve now or later; "each bridge will be crossed when we get to it." One thing we may state definitely: we do not intend to meddle with problems which deal with the termination of the present war. The exertion of our energies will be limited to that which is attainable by us. On the other hand, we contemplate dealing definitely with this one problem. At the termination of the war, or even at the mere sight of this termination, an attempt should be made to unite the medical men of all the neutral countries for the purpose of arranging an early international meeting of the medical profession, to which meeting some members of the profession of the belligerent countries, who have manifested through the war a more conciliatory, loftier spirit, may be invited to attend. We shall thus perhaps be in a position to accelerate an early rapprochement and fraternal reconciliation of the members of the medical profession of all the civilized nations. Here again we shall attempt to do our duty as we see it without being too sanguine as to an early and complete success.

Hippocratic Oath.—A few of our sympathizing correspondents wished to know whether the aims of the Medical Brotherhood are not already covered by the Hippocratic oath. No; that oath covers only the relations of the physicians to the individual as his private patient or pupil. As we all know, the influence of this oath leaves plenty of room for the ethical activities of the American Medical Association, the newly created College of Surgeons, etc. The Medical Brotherhood does not intend to deal with any part of this phase of medical affairs; it has in view exclusively the relations of the physician to his country as a patriot and to other countries as a humanitarian.

Patriotism and Medical Preparedness.—We have stated that medical men are in a position to be patriots and humanitarians at the same time. We have so far dealt exclusively with the international side of the Brotherhood. In fact, in the Appeal it was expressly stated "For the Furtherance of International Morality." However, it would not be

out of place to add a few remarks regarding patriotism and the relations of the physicians to it. The present war, while presenting a frightful picture of the bloody struggle between the nations, has revealed, on the other hand, a most remarkable ethical side of the relations of the individual to the State in each and every one of the belligerent countries. The readiness of the individual to be helpful to, and sacrifice himself for the State stands out as a shining light in the midst of the extreme darkness of the war. But here we wish to speak especially of the relations of our physicians to our country. Preparedness is a subject which at present agitates profoundly the minds of all of our citizens. It is none of our concern here to discuss this subject from the general point of view as citizens. As physicians, however, there can not be the slightest doubt that it is the duty of every member of the profession, who is in a position to do so, to offer his assistance to the medical department of the military organization of our country. We do not know when the country will be called upon to defend itself. It may come suddenly, like a bolt from the skies, which are surely not clear at the present time. Physicians who are not devoid of a sense of duty should, therefore, prepare themselves with the necessary knowledge and skill, and should in large numbers inform the military medical department of their willingness to serve in case of need. The hygienist, bacteriologist, internist, etc., can be of just as much service as the surgeon in the incidents of war. The medical man who marches with the scouts ahead of the army to select camps, to test the drinking water, etc., is as important as those who work behind the lines. And the medical man whose daily work brings him in contact with infectious and contagious diseases is trained in courage as high as the veteran of many battles; bacteria are as deadly as bullets; and in his daily work the physician, like the man in the firing line, never knows when they may strike him.

On the other hand, the practitioner knows now quite well what importance is to be attached to sympathetic psychical treatment of patients who are in need of it. A training to preserve humane-ness in the midst of passion and hatred ought to be a part of medical preparedness. After furious battles the poor injured prisoner of war needs often this mode of treatment as much as the surgical one.

The Medical Brotherhood of this country wishes to gather into its union those members of the medical profession who have a vein of idealism in them and who are willing to serve their country as patriots and humanitarians. It appeals further to the inspired ones to spread this gospel, wherever they find the proper opportunity, with impressiveness combined with patience and tolerance.

S. J. MELTZER, M. D.,

President of the Medical Brotherhood.

Diagnosis in Pulmonary Tuberculosis.—Lawrason Brown states that an appearance of ruddy health does not exclude tuberculosis, and that in any patient with constitutional symptoms, no matter of what he complains, the possibility of tuberculosis must be kept constantly in mind. Also the importance of physical examination in the diagnosis of this disease has been over-emphasized; symptoms are a better and more accurate guide to activity than physical signs. Symptoms without physical signs demand treatment, while physical signs without symptoms require only careful watching.—*Wisconsin Medical Journal.*

1. **Practical Points in the Prevention of Asiatic Cholera.**—Allan J. McLaughlin had the privilege of observing the work of sanitary officers during the outbreak of cholera in Germany in 1905 and during the cholera epidemic in Manila in 1908, at which time the disease broke out in Bilibid prison. In this institution there is absolute control of the food and water supply and ordinarily no fresh milk is used in the institution. The appearance of cholera in such an institution seemed inexplicable. It was quickly suppressed, however, following an order by the writer to compel thorough disinfection of the hands under guard upon leaving the latrines and before eating. At that time the writer made the statement that "The most important rôle in the transmission of cholera is played by the bacillus carrier." At this time 264 healthy persons were examined and seventeen were found carrying cholera vibrios, or a percentage of bacillus carriers among healthy persons of 6.44. During the last two years increased appropriations and personnel have enabled the Bureau of Sciences to extend greatly the search for carriers with splendid results. The writer has never known a bacillus carrier to harbor cholera vibrios for longer than twenty days, and the great majority lose their vibrios in less than ten days. However, other observers have found them present for longer periods.

Rapid methods of technique and an efficient system of collecting samples and handling the specimens make it possible for one person to examine 100 to 150 stools per day. Frank cases of cholera present little difficulty in diagnosis and are very much less of a menace in the spread of cholera than the carrier. Atypical cases, however, are much more serious as an epidemiological factor. These facts demonstrate clearly that the bacteriological diagnosis is our sheet anchor in preventing cholera, and it is the only means of diagnosis upon which one can rely. The writer accentuates the simplicity of the technique of cholera diagnosis and mentions some of the useless procedures to be avoided. The diagnostic procedures in Asiatic cholera may be limited to the securing from the feces of a discrete colony or pure culture of a vibrio and its agglutination by an anticholera serum of high titer. The agglutination should be performed with a serum of a titer of at least 1 to 4,000, and no weaker dilution than 1 to 1,000 used as a final test. Pfeiffer's phenomenon, complement fixation, and other biological reactions are useful aids, but are unnecessary for the simple diagnosis of cholera. Enriching fluids should always be used, good results being given by the peptone-enriching media. The use of gelatine should be avoided. Hanging drop procedures are time-consuming and of little value.

The author has never found a cholera vibrio freshly isolated from the human body which showed hemolytic properties or any marked variation in morphology, though these variations are found in laboratory cultures or strains isolated from water. He considers that the addition of Goldberg's media to our equipment would be a distinct advantage which would make the passage of an Asiatic cholera carrier through our quarantine still more unlikely.

8. Is Plastic Surgery a Lost Art? J. W. Keller.

1. **Serology and the Diagnosis of Syphilis.**—M. L. Heidingsfeld calls attention to a class of patients that have come to his notice in which a tentative diagnosis of syphilis has been made upon somewhat doubtful clinical evidence, which have been treated with salvarsan and neosalvarsan largely on the ground that the serological report from the laboratory was, in a measure, confirmatory. The laboratory report in most of these cases was "weakly positive" or "doubtfully positive." Under encouragement from the laboratory, antisyphilitic treatment is often pushed to extreme limits with negative results, and the patients eventually drift to the dermatologist for specialized attention. Within the brief period of eight days two such cases, which the writer reports, were referred to him. These cases served to illustrate that the general practitioner and the serologist can both fall into error in the management of many obscure dermatological conditions; that laboratory evidence, valuable as it may be, is not fundamental in character. In summarizing, the author states that the serological examination can never be positive in the absence of syphilis, unless through technical error; that a serological examination may be negative, and syphilis be present in clinically active or latent form; that both the Wassermann and the Hecht-Weinberg-Gradwohl tests are trustworthy, the Wassermann revealing the degree of early improvement and the Hecht-Weinberg-Gradwohl usually remaining positive long after the Wassermann is negative and thus measuring with much greater delicacy and precision the last traces of serological inhibition. A serological report must be either negative or positive; inhibition is either present or absent, and there is no place for a report "doubtfully positive." The diagnoses of dermatoses of doubtful nature or symptoms of uncertain character cannot be entrusted solely to serological evidence. Non-syphilitic dermatoses, resembling syphilis, may possess as associated syphilitic infection, which a positive serological report will invariably cloud with greater obscurity. The writer believes that serology has for the time being usurped the broader province of the clinician, and that the serologist must again yield to the syphilographer, the dermatologist, the neurologist, the internist, the oculist, etc., as the case may be, where there are questions involving doubt in the clinical diagnosis and treatment in syphilis. Serology is a mere aid to clinical diagnosis and therapeutics, and as such belongs strictly in the province of the clinician of syphilis.

3. **The Colloidal Solutions of Silicic Acid.**—S. P. Kramer describes his observations on the physiological action of these solutions. He finds that when solutions of colloidal silicic acid are injected into the jugular vein of rabbits or dogs, under certain conditions, death of the animal occurs by intravascular clotting of the blood. This will occur more readily the more concentrated the solutions are and the nearer the dilute solutions are to gelation. Animals killed by these injections show the right heart and pulmonary vessels filled with clot. The lungs are infarcted, and the acini show the microscopic picture of red hepatization. There are other striking reactions *in vitro*. If colloidal silicic acid is added to washed sheep red cor-

puscles in the proportion of 1 to 500,000, or even 1 to 1,000,000, a prompt precipitation of all the red corpuscles takes place. If to fluid cultures of colon bacilli colloidal silicic acid is added in the ratio of 1 to 10,000, agglutination and precipitation of the bacilli takes place. If urine, to which has been added silicic acid in amounts equal to 1 to 5,000, is allowed to undergo acid fermentation, the urates and the silica are precipitated as a gelatinous "stone." This precipitate is insoluble on heating. If a solution of Victoria blue B is added to a solution of colloidal silicic acid, a blue precipitate is formed, insoluble in water and dilute mineral acids. This reaction may be used for the demonstration of exceedingly minute amounts of silicic acid. Mucus is rich in silica, and is deeply stained with Victoria blue B. This staining is acid fast. The same is true of cartilage and elastic tissue. No silica could be found by this reaction in normal blood serum or in hydrocele fluid. By adding very small amounts of the dye to cerebrospinal fluid the writer has been able to demonstrate the presence of silica therein. If a drop of 1 per cent. solution of the dye is added to 10 c.c. of cerebrospinal fluid, and this is allowed to stand a few hours, there is formed a blue precipitate. It was found that the amount of silica varied in different diseases. The intravenous injection of dilute solutions of silicic acid in amounts insufficient to cause death of the animal, causes an increase in the flow of cerebrospinal fluid.

6. The Malingering.—Daniel Hale Williams says that malingering is a part of the social problem; it is composed of a group of lesser problems, the economic, educational, religious, political, and moral. The solution of these lesser problems is the solution of the whole moral problem, for the malingeringer is the product of abnormal conditions in these phases of the social problem. One of the considerations which makes the malingeringer so reprehensible is his bad example and influence upon others. Perhaps no better illustration of his far-reaching and sinister influence can be found than his influence on the medical profession. The influence of the malingeringer has preyed upon the physician just as it has upon the individual by holding before his professional eyes the charms of large and easy fees. This influence is to be feared and dreaded because of the number of weak men in the medical profession who are unable morally and professionally to withstand the allurements of false monetary rewards. This fraud and falsehood within the ranks of the profession lowers public confidence in the whole profession. The malingeringer is an equal menace to the legal profession and to society. The Workmen's Compensation Act may be instrumental in abolishing the malingeringer. The idea involved to this end is the appointment, by the executive power, of a board of three or more with jurisdiction, by agreement of both parties or upon the election of either, to determine the extent of injury to any person hurt by accident in certain named industries, with a right of appeal to the Circuit Court. One of the distinguishing features of this act in the State of Illinois provides for the selection of a physician by the injured, one by the employer, and a third by these two, or by the board to examine the injured person and report to the board.

2. Medical Education with Reference to Rural Communities.—Gordon Wilson says there is no question today but that the American people are receiving vastly better medical attention than they did ten years ago, but already the cry for a doctor is coming from rural communities, and they are asking for a good doctor if possible, but in any case "a doctor." It is his opinion that there is need in this country of two classes of medical schools, the one, modeled after the Johns Hopkins, in which the requirements can hardly be set too high, and the other and larger class for the training of the practitioners of medicine. The first type of school should have an absolutely self-limited number of students, and they should be thoroughly trained not only in clinical and laboratory medicine, but also in the methods of research. Naturally the men who graduated from such a school would become teachers, research workers, and specialists, and practitioners and consultants in the larger towns and cities. To require the foregoing of all men who desire to practice medicine would undoubtedly raise the standard of the profession, but in the long run it would prove no more satisfactory than that locomotive engineers should be graduates in mechanical engineering from an approved college. The second type of school, in the opinion of Dr. Wilson, should demand for admission that the applicant be really grounded in the essentials of a good education, namely, the requirements for admission to most colleges in English and its branches, history, mathematics, chemistry, physics, and biology. The knowledge of a modern language is a help, but never an essential. This second type of school should give a full four-year course, and the work should have little of the elective in it. The clinical and laboratory courses should be of the very best, but the time devoted to research work should be limited to a minimum. A study of the physicians practising medicine in rural Maryland shows that there are only four graduates of Johns Hopkins practising there, while there are 350 graduates of the University of Maryland School of Medicine, 88 graduates of the College of Physicians and Surgeons, and 59 graduates of the Baltimore Medical College, who are practising in the Maryland counties. In the opinion of the author these figures justify the belief that graduates of a school like Johns Hopkins will only exceptionally settle in the country, and that we must make the premedical requirements less exacting in time, although, perhaps, they may be raised along certain lines above to-day's standard, and any increase in the requirements must be made slowly and gradually and only after a most careful study of all possible consequences. He believes that we are facing a real and dangerous shortage of doctors, the need of whom will be emphasized by the large number of physicians required for an enlarged army and navy, and the putting into force of the whole-time county health officer advocated by many authorities.

3. Some Further Developments in a Pediatric Department of a University Medical School.—William Palmer Lucas outlines the history of the growth and development of pediatrics in this country, and points out that for the further development of this branch of medicine it is important that the pediatric depart-

ment of a university should be in close relation with the department of nutrition and dietetics; with the academic department of psychology, as this has a direct bearing on all the problems connected with mental defectiveness; with the department of social economics; with the department of education, and the department of physical culture. Thus far the pediatric department of the University of California has established a close relationship with three academic departments of the university; a trained psychologist is a member of the pediatric staff and at the same time holds a position in the department of psychology; the department of nutrition and dietetics, and the department of social economics. The usefulness of these departments has been mutually broadening, and the work of educating the necessary workers for these fields has been put on a stronger basis. The writer points out the need for and the advantage of co-operation between pediatric departments and all public and quasipublic institutions dealing with the problems of infancy and childhood, and says that a point of contact which very few pediatric departments have made, and one which is of importance, is the juvenile court, state reformatories for juvenile offenders, and state homes for feeble-minded children. Further points of contact between a pediatric department and the larger problems of childhood would be a more intimate connection with the recreational and vocational problems which are now being studied in all progressive communities. It is, therefore, incumbent on medical schools to offer just as wide and practical a field to their students as possible, and for the future physician the broader the contact with concrete problems during his period of training, the sooner will he be able to make his own definite contribution to medical life as he in turn meets it in the home, school, hospital, and community.

6. Craniopharyngeal Duct Tumors.—Harry Jackson says that tumors arising from rests of embryonic tissue along the course of the craniopharyngeal duct have not received adequate or proper recognition, although they represent the most common type of heteroplastic tumor of the hypophyseal region. Only three authentic cases of this type of growth in which the genesis of the tumor has been recognized have been reported in this country; to these he adds a fourth case, and discusses the history, embryology, pathology, etiology and symptomatology, diagnosis, prognosis, and treatment of these growths. From a study of 38 cases in the literature he concludes that most cystic and solid tumors originating from the region of the infundibulum and anterior lobe of the hypophysis grow from embryonic rests of buccal ectoderm from the craniopharyngeal duct. They are the most common type of intracranial tumor associated with the Frölich syndrome. Eye symptoms occur early. Symptoms of acromegaly are absent. Some cases reach the acute stage in three or four weeks, while others admit symptoms lasting over a period of years. The active treatment of this condition is as yet unsatisfactory. It is surgical and consists in the puncture and drainage of the cyst by a trans-sphenoidal route. These cysts usually cease draining and produce pressure symptoms and blindness after weeks or months. It seems impossible to eradicate all the cyst wall, although an attempt should be made to cut away as much as one can without injury to the surrounding parts. Lately, the injection of the extract of the posterior lobe of the hypophysis has been used, the idea being to absorb the contents of the cyst. Some clinicians report good results by this method, although theoretically it is difficult to account for such improvement.

10. Typhoid Vaccination.—Paul G. Weston reports

that he has administered the routine immunization against typhoid fever to 3,500 patients in an institution for the insane in Warren, Pa. In this institution inoculation is voluntary for the attendants and compulsory for the patients. At first all patients over 50 years of age were excluded, as well as the patients who presented distinct contraindications. But shortly after the immunization of the first series of 898 patients, two cases of typhoid developed, one in a woman 65 and the other in a woman 70 years of age. Since that time no patient has been exempted on account of age. Since immunization has been made a routine procedure only one case of typhoid fever has developed, and that an exceedingly mild one. The vaccine used was made from the same strain as that used in the army. The suspension of bacteria was made so that 0.5 c.c. contained either one-half billion or one billion bacilli. Three doses are given each patient, at intervals of ten days, the first dose containing one-half billion bacilli and the second and third doses each containing one billion. Newly admitted patients were not immunized at the time of admission, but at intervals of six months all patients admitted during that time were inoculated on the same day. In all, 10,500 inoculations were made. Many of the patients slept through the inoculation and knew nothing of it until the next day. In this number of inoculations there were only eight reactions that could be considered severe. Since the duration of the immunity is unknown, the writer says it is not his intention to reinoculate any patients unless typhoid makes its appearance among the immunized. It is now three and one-half years since the first inoculation and but one case of typhoid fever has developed in an inoculated patient, and that occurred three months after inoculation.

3. Some Notes on the Treatment of the Turkish Wounded from the Suez Canal. Frank Cole Madden.
4. The Treatment of Hemorrhoids by Injection. Arthur S. Morley.
5. The Prognosis in Sympathetic Ophthalmia. Percy Dunn.

1. The Pituitary Fossa and the Surgical Methods of Approach to It.—V. Zachary Cope reviews the comparative morphology and development of the pituitary body in man, the normal and pathological anatomy of the pituitary fossa, and the methods of approach that have been utilized by different surgeons. He says that there are only four of these methods which have been practised on a sufficient number of cases to merit special attention. These are Horsley's temporal method, Schloffer's coarse nasal operation, Hirsch's and Cushing's submucous septal approach, and Frazier's fronto-orbital route. He shows that the nasal, the palatal, and the method of approach through the ethmoid by an external incision are fundamentally unsound since they leave open surfaces, which take a long time to heal and which are a constant danger of infection, and, in addition, considerable deformity to the external nose may follow. There are two operations, however, which have proved fairly satisfactory for approaching the pituitary fossa, The Hirsch-Cushing submucous nasal method, and the fronto-orbital method of Frazier. Though it is not possible yet to decide finally between these, there is some reason for the belief that the fronto-orbital route is more suitable in the great majority of cases. In three cases in which the writer has operated this method has been adopted with success. All three of these cases were almost blind before

brought to operation. In the first case a portion of an endothelioma was removed and the general condition improved, though the sight did not improve. The third case obtained great improvement of vision after a cyst was evacuated. The second case proved to be one of syphilitic meningitis, and though the patient said he was a little better after operation there was no obvious improvement in his condition. Now that the mortality of the operation has diminished surgeons can more readily urge that patients with on-coming blindness due to pressure on the chiasma should be treated by operation more early than is now the case.

4. **The Treatment of Hemorrhoids by Injection.**—Arthur S. Morley relates his experience in the treatment of a large number of cases of hemorrhoids of all degrees of severity by injection. He says he at first employed the method on what might be described as medium cases, in which there was very moderate and occasional bleeding, slight prolapse, and slight pain on defecation, but owing to limited hospital facilities he extended the treatment to cases that he had considered suitable for operation and found that in an enormous majority of them all symptoms ceased like magic after a few injections. The treatment consists of the injection into each internal pile of a few drops of carbolic acid and glycerine, the following solution being used: Acid. carbolic, gr. xlviii; glycerin, dr. ii; aquæ destillat, dr. ii. The injection is performed through a large speculum by means of a modified Dawson's dental syringe, having a bore needle about three-eighths of an inch long, fitted into an elbow-shaped socket. The only other essential is a really good light. Before making the injection the piles are sponged over with a weak solution of biniodide of mercury or 1-50 lysol solution, and then touched at the spot where the injection is to be made with pure carbolic. In making the injection the needle should be pushed up along the long axis of the pile to near its base; usually this means entering the needle to its full length. The needle is not withdrawn at once but allowed to remain in position for some 30 seconds until the pile has commenced to swell and become blanched. The treatment is not suited to cases of strangulated or irreducible hemorrhoids, or to cases in which there are complicating conditions, such as old-standing fissures, fistulæ, ulcers, etc., or to cases that have become partly polypoid from previous attacks of thrombosis. It is important that the patient be instructed to keep quiet, if possible in bed, for the first twelve to twenty-four hours after injection. The obvious advantages of the treatment are: "(1) that the patient need not lie up for more than at most twenty-four hours; (2) that there is no need for either general or local anesthesia, since the treatment is practically painless, if properly performed; (3) that it can be made quite inexpensive, so much so, that it may be brought within the reach of even a quite poor patient, who certainly could not face the expense of an operation in private; (4) that it is a perfectly safe procedure in patients, such as the very aged, pregnant women, and others who for some reason cannot take an anesthetic safely, such as persons with dangerous heart or lung diseases; (5) that there is no after pain, and (6) that it is, as far as I have seen after employing it in a very large number of cases, invariably harmless."

1. **The Importance of General Principles in Military Surgery.**—G. Grey Turner writes from a large experience with the wounded returned from Flanders or the Dardanelles. He says that while books are being written on military surgery, schools are being set apart for its study, and it is commonly spoken of as apart from everyday surgery, the principles which underlie surgical practice in general are exactly the same as those which govern the injuries met with as the result of modern firearms. In nearly all the reports from the seat of war the need of guidance by general principles is being recognized. The peculiarities which undoubtedly exist are those of environment rather than any inherent peculiarity in the wounds themselves. The wounds are often inflicted under filthy conditions, the wounded may have to lie for hours, sometimes even for days, before receiving any attention whatever, and the range of modern artillery is so great that the attention they then receive is only in the nature of first aid, and the nature of the wounds makes them exceedingly difficult to cleanse even under the best possible circumstances. Hence, practically all the wounds treated in the home hospitals have been septic. The method of drainage is important, and although tubes are undoubtedly the best means, there are abuses and dangers connected with them which we have learned in the surgery of civil life to avoid. They ought not to be too big, and should be removed the moment they have served their purpose. Counter openings are very useful and cannot always be superseded by the use of tubes. Another principle which we have relearned during the last few years is the importance of fresh air in combating infections. The writer has found that his septic cases improved enormously when kept on a balcony or in open tents both day and night, and believes that no one factor is of more benefit to septic patients than the free use of the open air. He emphasizes the importance of removing the focus of infection before resorting to vaccines, and in this connection says that for many months they have not had a single case of tetanus due to the fact that the wounded men are all getting prophylactic doses of antitetanic serum. The reopening of healed wounds and sinus formation are often due to a definite and tangible cause such as a foreign body or the formation of a sequestrum. In the great majority of instances it is a wise thing to remove a foreign body if this can be done without running any grave risk so far as the life of the patient or the function of the affected part is concerned. Although it is a psychological matter in many cases, it makes all the difference in the world to a man whether his foreign body is in his chest wall or his waistcoat pocket. Certain principles must be always kept in mind. First you must recognize that if you cannot do any good you have no business to run the risk of doing serious harm. Secondly, no one should undertake the removal of a foreign body without very careful consideration as to its exact position and relation to surrounding structures. An operation should never be carried out without an x-ray examination. As the foreign body is always potentially a source of infection, the area from which it is removed should always be drained. Some simple devices have been found most useful in x-ray work. For instance, it has been observed that when a foreign body is near the surface it can easily be made to move by pressing over

its site during a screen examination. A screwdriver used as a pointer is very useful, and wires have been found of value in the localization of bullets in the chest and in the head. One should always beware of ill-considered attempts to remove small foreign bodies embedded in muscular parts, since they are scarcely liable to give much trouble in such locations. The writer states that on four occasions he has deliberately opened the chest and removed a bullet or shell casing, and in each case with complete recovery. In the treatment of compound gunshot fractures a most important point is to resist the temptation to remove loose fragments since bone is the best stimulus to the formation of new bone, and it is impossible to say how much bone will live or die, and in most instances nature spares more than one would expect. A good deal of evidence is still required to demonstrate that it is good practice to use screws and plates in compound fractures. In dealing with fractures of the forearm the important point is to keep the bones of the forearm fully supinated. It does not matter much how the arm is put up to secure this full supination. Fractures of the lower end of the femur with backward displacement must be met by flexion of the knee, as neglect of this precaution may give rise to a very crippling amount of disability in the movement of the joint. It is important to deal with injuries of the joints in such a way that should an untoward result follow the limb will be in a useful position. This rule should be followed whatever the cause of the joint injury, but is especially exemplified by numbers of cases met with in military practice. More rest and less massage is a very sound axiom in military surgery of bones and joints. Finally, the writer emphasized the importance of cheerful surroundings and of hope as one of the most valuable and cheapest remedies we possess.

Arthritis Deformans and Accidents.—Senger writes with special reference to this affection as it concerns indemnity claims. He has had occasion after years of accident practice to modify his conception of it. Older authorities looked upon the affection as final, beyond all hope of a *restitutio ad integrum*. If this is true an accidental origin of such a condition means a life income for the victim. Authorities even if agreed on prognosis differ greatly in their conception of the disease. Hoffa makes sharp distinctions between it and chronic polyarthritis. The latter begins in the soft parts, the former in the skeletal parts. In this distinction he is followed by most general surgeons. Axhausen claims that arthritis deformans begins with necrosis of the joint cartilages, which leads to proliferate changes. This necrosis is practically of traumatic origin. The latter, however, must be demonstrated clinically and in the clinic all joint affections present a close resemblance. Can trauma explain the simultaneous development of the disease in several large joints? Why should the palmar and plantar aponeuroses participate? Why does the disease develop insidiously without local factors? These questions are suggested by Ledderhose's conception of the disease, which however is not admitted by the majority who agree that one large joint is usually attacked, and that the aponeurotic lesions are only coincidental. They also lay great stress on *x-ray* finds. While Ledderhose does not pay much attention to these. The author relates cases of accidents immediately followed by arthropathies. After prolonged treatment with improvement the inconic was reduced. With eventual diagnosis or arthritis deformans victims were pronounced permanently in-

valided to a certain extent (25 per cent., 20 per cent., etc.). In these cases the disability was established largely by the permanent *x-ray* pictures. The author concludes that arthritis deformans is of much more common occurrence than has been assumed and that syphilitic osteochondritis is not differentiated from that disease in the clinic. He goes further and claims that arthritis deformans must henceforth be regarded as a symptom, and no longer as a disease. It is of course quite intelligible that the syndrome may follow a trauma. In testing these cases for a syphilitic substratum the author obtained a positive Wassermann. The patient was young and the accident relatively recent. The *x-ray* showed that the joint lesions were not fully developed and recovery occurred under salvarsan. Such cases are far from uncommon and hold out a hope for recovery.

Wholesale Poisoning from Nitrites.—Zadek describes an episode in which a number of firemen in the exercise of professional service were forced to inhale the fumes of nitrous acid, the containers having exploded in the midst of a conflagration in a warehouse. The streams of water poured upon the blaze increased the quantity of fumes. The men, eleven in number, continued to work despite the latter, although some were obliged to put on their smoke helmets. The flames were extinguished, the after duties performed and all the men went home and ate heartily. At 11.30 P.M. all hands turned in. Within three hours the majority awakened ill with headache, nausea, and diarrhea. There also developed insomnia, vertigo, and severe headache. All the number were eventually interned in the hospital, the most striking symptom being marked air-hunger with intense cyanosis in the worst cases. The brunt of the attack was sustained by the respiratory and alimentary tracts. The sensorium was clear. Despite the most active treatment the three worst cases were in severe peril for a long period, and one died in coma. These three men, unlike the others, developed delirium. All the nitrites when given in sufficient amounts are severe blood-poisons which change oxyhemoglobin to methemoglobin. This alteration was readily recognized in the fatal case.

Clinical Contribution in Reference to the Demonstration of Occult Blood in the Stomach Contents and Stools in Cancer of the Stomach.—Emmert examined twenty-one cases of cancer of the stomach. Occult blood was found in twenty. No other affection shows such an incidence. The symptom is a very early one, and should be present by the time the patient has come to consultation. In one case a positive result was obtained in four weeks after the beginning of the symptoms. Operation revealed an induration as large as a thaler. In another case the presence of cancer was revealed in a clinical picture of gallstone disease. Occult blood in the stomach contents excludes an intestinal lesion. The procedure usually employed is the guaiac test; in fact a positive guaiac points strongly to cancer while a negative guaiac—even a single test—practically excludes cancer. Applied in cases of chronic ulcer and ulcer scars, the appearance of blood marks a transition to cancer. In twenty-six cases of gastric or duodenal ulcer which came to operation not one showed occult blood in the stools; while only in three recent hemorrhagic cases of duodenal ulcer was there a positive result. The author, however, modifies this assertion by stating that in seven cases before treatment was begun there was occult blood in the stools, but this quickly subsided after rest and diet.

Epidemic of Recurrent Fever Treated with Salvarsan.—Prussian states that relapsing fever is a subject which possesses double interest. It is a disease of mankind due to an organized specific cause and it can be destroyed in the body by salvarsan—a true sterilisation magna. This discovery of the action of arsenobenzol on a spirillum was in fact the cornerstone of the syphilis treatment with the same substance. In a Russian hospital relapsing fever broke out in 1915, appearing at first sporadically. At first unrecognized its nature was finally recognized by the fever curve and discovery of the spirochete in the blood. The disease continued to spread until there were nearly 400 victims. The infection had apparently originated in a prison camp close by, and in any case is endemic for the locality. It was readily learned that the disease is louse-borne, but while in typhus one louse bite can convey infection in relapsing fever a patient must have become very lousy to become infected. Hence physicians and attendants do not have to suffer, and but one of the latter—the dirtiest and least intelligent—became infected. Before the proper diagnosis had been made numerous cases had received no specific treatment so that an excellent chance for comparison developed. The fever curves in the two sets of cases showed marked differences. Salvarsan even in one intravenous injection completely jugulated the disease save in 5 per cent. to 6 per cent. of all cases. The characteristic recurrence of fever was completely straightened out save in these exceptions. The reasons for such problematic behavior cannot even be surmised, unless due to the fact that the spirochetes have become included in cells somewhere in the body and thus have become unable to use their arsenoceptors.

Pneumococcus and Meningococcus Meningitis after Fracture of the Base of the Skull.—Schmidt relates the following case which he regards as of unusual interest. A workman aged 19 sustained a fractured basis cranii from a fall on the stairs and was rendered unconscious. Thereafter there set in great restlessness, fever, stiff neck, divergent strabismus, and painful sensations. There had been an interval between the accident and symptoms, but its length is not stated. Patient was interned at the clinic on the seventh day, and succumbed on the following day. Specimens of blood and spinal punctate had been obtained before death. From the cerebrospinal fluid both pneumococci and meningococci could be cultivated. The former could also be seen in blood agar plates. The presence of the meningococcus could also be demonstrated serologically. Autopsy revealed a fracture through the bony roof of the sphenoid with an adjoining fissure into the ethmoid. There were clots and bloody mucus in the sphenoidal sinuses. The dura was intact. Quite extensive leptomeningitis was seen in the cerebellar and positive regions. The mucosa of the upper portion of the nasal fossæ was swollen and markedly reddened. There were a number of foci of a bronchopneumonia of three or four days' duration in the lower lobes of the lungs. All the evidence pointed to a blood metastasis and lymphatic propagation seemed out of consideration. The accident led to hemorrhage into the sphenoidal sinuses, and this furnished an ideal culture medium for the germ life which gained access to it through the fracture. These germs excited no pyogenic or other inflammatory action *in loco*, but this fact the author does not regard as prejudicial to his reasoning. The pneumococci in the blood were presumably derived from the cultures assumed to be present in the sphenoidal sinuses. The bronchopneumonia was probably due to aspiration of nasal secretions during the original period of un-

consciousness. The author assumes that the cocci of both kinds reached the spinal fluid through the blood. He does not assume that this case throws any light whatever upon the rationale of epidemic cerebrospinal meningitis, and is inclined to accuse a lymphogenic origin of the latter in the majority of cases, although a minority present a parallel is the author's case.

Etiology of Weil's Disease.—Weil, who originally described this affection, is naturally much interested in recent reports concerning its etiology and the more so because he himself is no longer situated to pursue research along these lines. He had never made any bacteriological studies at any time. The cultivation of a specific microorganism from the blood is of great importance but the author seems very conservative if not somewhat sceptical as to its causal role. The disease transmitted to guinea pigs cannot straightway be termed Weil's disease. While much flattered and honored because the affection under discussion was named for him, it might be better to adopt the designation originally proposed by him of an "acute infectious disease with splenic tumor, icterus and nephritis." His intention, over 30 years ago, was to erect a group disease with these lesions—this triad so to speak—of which "Weil's disease" was to be a member. But not all authors chose to adopt this designation. Some have used such terms as "febrile icterus" and "febrile jaundice," but these are far from being equivalent to "Weil's disease." Catarrhal icterus may be present in many fevers. To consider the summation of the picture of Weil's disease it is necessary to enumerate a characteristic fever type, icterus, splenic tumor, albuminuria, cerebral manifestations and severe muscular pains especially in the calf muscles. The author has read of a case of Weil's disease following traumatic erysipelas. It is well enough to regard such spurious cases as belonging to a clinical group disease of which Weil's disease is a member; but the latter term should not be applied to such cases. Once the typical disease has been established in all respects we can begin to formulate abortive and other irregular forms. For the present an inoculation type of the disease on animals cannot yet be regarded as the true malady, because in mankind, as all along stated, we see conditions enough which only resemble superficially Weil's disease. In the same number of the Wochenschrift Hübener and Reiter conclude a serial article on the etiology of Weil's disease. They assert that the latter as studied by them agrees in all respects with the original Weil's disease as first described over 30 years ago. It is an acute, non-contagious, infectious disease, the exciting cause of which is a spirochaete, conveyed to mankind through insect bites directly into the blood, in which specific toxins are formed, and the internal organs attacked so that a general disease is set up with typical fever and damage to the kidneys and liver. In regard to the existence of atypical and abortive forms the authors expect to be able to show that such exist. The results of inoculation experiments involve too much time for rapid diagnosis, but thus far the authors have been unable to obtain serological reactions.

Daily Food Ration of Great Britain.—Langworthy placed the energy value of the daily food ration (year 1908) as purchased for moderate work at 3,800 calories. The ration contained a remarkably large amount of fat. Thompson drew two conclusions from this (1) that the tendency in urban and industrial populations is to increase the fat at the expense of the protein, and (2) that the ration could not be reduced without endangering the efficiency of the working man. The substitution of vegetables as protein sources instead of meat would relieve the cost.—*The British Medical Journal*.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON PEDIATRICS.

Stated Meeting, Held February 10, 1916.

Dr. ROYAL STORRS HAYNES, IN THE CHAIR.

A Case of Complete Cretinism with Normal Mentality.

—Dr. WARD B. HOAG presented this patient, a girl $5\frac{1}{2}$ years of age, who had first come under his observation when she was $3\frac{1}{2}$ months old. At that time she had all the typical characteristics of cretinism. Her extremities were the shortest he had ever seen. Her head was covered with a thick mass of coarse, flaxen hair, her nose showed no development, her tongue protruded, her skin was dry, and her flesh showed no resiliency. She showed no animation, even hunger apparently forming no part of her desires. At the present time she stood 40 inches in her shoes and she weighed 43 pounds five weeks ago, which was more than the normal weight and height of the average child of her age. There was apparently nothing abnormal in the condition of the child at the present time; she played and talked just as any other child. The absence of the thyroid could not be attributed to trauma, since there was nothing abnormal at the time of birth except that the labor was rather precipitate. Dr. Hoag said thyroid medication was begun at the time he first saw the child, $\frac{1}{4}$ grain of thyroid extract having been given twice daily. This amount was gradually increased until for a time, when she was about four years of age, she took 5 grains daily. Under this amount she developed the typical signs of excess of thyroid. For some months she had been getting 3 grains daily. Very soon after beginning the thyroid treatment her hair came out in great masses and her skin came off in sheets, two or three inches coming off in one piece, and the child was practically made over in a few weeks. Dr. Hoag thought she was worth while presenting as demonstrating the result of thyroid medication together with persistent and careful attention on the part of the mother. The case showed that if one took a case 100 per cent. cretin early and administered the amount of thyroid that nature intended the child to have, one could get a perfectly normal child, provided the child had no other defect in any other ductless gland secretion.

Dr. THOMAS S. SOUTHWORTH said that in this case he would put the stress a little differently from where Dr. Hoag had placed it. He would say that the case showed what could be done if one got these cases early enough. They had all seen cases coming to treatment later in which a considerable degree of improvement was obtained, but the success obtained in this case was due to the early age at which treatment was begun, and the important point lay in getting these patients before the mental damage was done.

A Case of Death Following Ingestion of One Dram of Camphorated Oil.

—Dr. SIDNEY V. HAAS reported this case. He stated that the almost universal use of camphorated oil as a household remedy made a knowledge of the danger attending its internal administration important. Camphorated oil was a preparation containing 80 per cent. cotton-seed oil and 20 per cent. camphor. The literature abounded with reports of deaths due to the ingestion of this preparation. These reports showed that the amounts that had resulted fatally varied. Death had resulted from taking $7\frac{1}{2}$ grains of camphor; on the other hand, an instance had been reported in which a child had taken a teaspoonful of the oil upon a full stomach and was then given a teaspoonful of castor oil and all went well. The case he wished to report occurred in a baby three weeks old. The baby was brought to the hospital three-quarters of an hour after having been given a teaspoonful of camphorated oil by mistake. (The baby had a slight bronchitis and the physician had prescribed castor oil internally and camphorated oil externally.) The child was cyanotic and appeared to be very ill. The stomach was washed out and the child was placed in a ward and at this time did not appear very ill. The maximum temperature was 100.6° Fahr. The child only showed signs of bronchitis which had been diagnosed before the camphorated oil was administered. After about forty-three hours the child died very suddenly in a cyanotic attack. This was in accord with observations previously made that death from this cause usually occurred within forty-eight hours. The urine in this instance showed a

slight trace of albumin. As an explanation of the toxicity of camphor in young infants and weakened children, it might be mentioned that C. Happich, in experimenting on rabbits and guinea pigs, found that the degree of tolerance for camphor depended upon the presence of glycuronic acid which was produced in the pulmonary circulation, by the combination of sugar and oxygen. In states of inanition this substance was much reduced and the individual became more susceptible to the toxic action of the drug.

Differential Diagnosis of Thoracic Conditions by Roentgenogram.—Dr. LEON T. LEWALD gave a lantern-slide demonstration in which he first showed what was revealed by the roentgenogram in pneumonia, and called attention to the possibility of confusing these with old tuberculous bronchial lymph nodes. He then showed a picture which was suggestive of miliary tuberculosis, but was probably a tumor, possibly a sarcoma, of slow growth, and said that such a picture was instructive in emphasizing the importance of taking into consideration the clinical history of the case and the possibility of making a mistaken diagnosis from the radiograph alone. Dr. LeWald next showed pictures of anomalous ribs, cervical ribs, and transposition of viscera, and stated that he had seen fifteen instances of transposition of viscera. Other slides showed foreign bodies located by means of the roentgenogram. In one instance the foreign body had been lodged in the bronchus for seven years, and the patient had been operated on for empyema; in another case, a child was operated on for an encysted empyema, and the condition was found to be due to an upholsterer's tack which had been swallowed two years previously. If one had to deal with a condition of this kind which would not heal it was always advisable to subject the patient to a roentgenological examination. In making radiographs in looking for foreign bodies it was a help to take plates in the lateral or oblique positions. Dr. LeWald also called attention to the possibility of mistaking a beginning pneumonia for an acute appendicitis and related a additional case together with the case described before the Joint Meeting of the New England Pediatric Society, the Pediatric Section of the New York Academy of Medicine, and the Philadelphia Pediatric Society (MEDICAL RECORD, January 22, 1916.) Both of these cases were under the care of Dr. J. Finlay Bell of Englewood, N. J., and to him belonged the credit for the suggestion of making the differential diagnosis by means of the Roentgen ray.

The Diagnosis of Congenital Pyloric Stenosis of Infancy by Roentgenogram.—Dr. LEWALD read this paper and illustrated it with lantern slides. He said that Dr. Downes had operated upon seventy-seven cases of pyloric stenosis in infants. Forty-seven cases belonged to a recent series in which he had performed the Ramstedt operation. Thirty cases were in the earlier series in which a gastroenterostomy was performed. The age of the children ranged from fifteen days to four months. In Dr. Downes' series there were four males to one female. As to the choice of operation, it had been the experience of both Dr. Downes and himself that the Ramstedt operation of simply splitting the hypertrophied muscle allowed the stomach to empty itself in a more physiological manner, while the performance of a gastroenterostomy was likely to produce too rapid emptying of the stomach and intestinal disturbance. According to Dr. Downes' statement, this had been observed in 50 per cent. of the cases in which the latter procedure was employed. After speaking of the attempts to classify the different degrees of pyloric obstruction and of the ingenious theories that had been advanced to account for its origin, Dr. LeWald said that a study of the literature on this subject forced one to the conclusion that, after all, little had been gained and that these theories did not assist very materially in an elaboration of diagnosis nor to establish a definite form of treatment, which was the important and practical end that was sought. Certain cases which exhibited the classical symptoms, namely, projectile vomiting, steady wasting, constipation, excessive stomach peristalsis, in addition to a palpable nodular tumor in the pyloric region, must be regarded as cases of true pyloric stenosis. On the other hand, cases were reported without any palpable tumor, but otherwise having all the usual symptoms in varying degrees of severity. It was perhaps in these that the greatest difficulty arose as to the best method of procedure and in how far they might be surgical. The suggestion was given by the majority of workers that this group should be treated medically until they no longer re-

spond to medical management, as evidenced by stationary or falling weight. They might then be subjected to laparotomy with its high degree of hazard, the operator being necessarily uncertain as to his method of procedure until he had satisfactorily explored the stomach. If a hitherto undiscovered tumor was found at operation, the infant must be able to stand a considerable degree of shock incident to the performance of a posterior gastrojejunostomy. If no tumor is found, little was gained and much lost by subjecting the impoverished infant to the loss of blood and further depletion of its natural resistance. If, therefore, by the use of modern methods diagnostic means could be made so complete that we could with a degree of positiveness determine whether or not a given case should be operated on, we should be making an advance worth while. Modern apparatus with the intensifying sheets enabled the radiologist to make instantaneous exposures, thus securing with the minimum effort negatives of great value. Whether the stomach in early infancy was simply a dilated pouch for the accumulation of food which was quickly acted upon by the gastric juice and immediately allowed to pass out through the pylorus, or whether it performed its share of the preparation of food for the more complex processes of digestion in the duodenum was a question for future study. The fact was that they might observe the exit of food into the duodenum within a minute or two after its intake, and this tended to show that the stomach played a part which had been overvalued. That liquid foods began to be expelled normally in a very short time after they were taken into the stomach was very helpful in making a diagnosis of the conditions under consideration, for if it could be demonstrated with a degree of exactness, by a series of radiographs, that the milk was retained for a greater length of time than in the normal stomach, as was shown by the bismuth shadows, the type of obstruction with which one was dealing could be determined with a fair degree of certainty. Since these striking results could be obtained it seemed manifestly unfair not to early obtain a series of radiographic pictures in every case suspected to be one of pyloric stenosis, so that an infant suffering from a true tumor and lumen so small as to practically occlude the passage of food into the duodenum might be early given into the hands of the surgeon while its physical condition was still good. Again cases of pyloric spasm, even of marked degree, but without tumor formation, could be differentiated, since the amount of food passing through the pylorus and the time required for its passage could be seen and thus the diagnosis and even the prognosis could be fairly well fixed. The prophecy might be made that in the future every suspected case of pyloric obstruction would be subjected to radiographic study before determining on a plan of treatment, just as today no surgeon thought of putting up a fracture without the use of the *x*-ray.

Recurrent Hilus Infiltration: An Unusual Form of Tuberculosis in Children.—Drs. MURRAY H. BASS and HENRY WESSLER presented this paper which was read by Dr. Bass. He stated that our knowledge of the pathogenesis and anatomical varieties of tuberculosis in childhood had undergone considerable change during the past decade and at present it is recognized that the clinical types of pulmonary tuberculosis in the first few years of life were quite distinct from those of adults. There were, however, forms of tuberculosis whose localization in the lungs of children was just as typical as that in adults, the area of lung involved being determined by the presence of the diseased bronchial nodes. After reviewing the generally accepted conception of the origin and distribution of tuberculosis in the infant and child, based on the work of Hamburger, Gohn, and Albrecht, Dr. Bass said that recurrent hilus infiltration was an extension of the tuberculous process from the lymph nodes and occurred often enough to be recognized as a clinical entity in the great group of tuberculous infections of the lung. Sluka had encountered it thirty-eight times within a few years and Eisler had also reported an identical clinical picture. For a knowledge of the morphology of this lesion they were indebted to the Roentgen ray. It occurred in the vast majority of instances on the right side and its point of predilection was in the lung in the immediate vicinity of the fissure between the upper and middle lobe. Beginning with its base at the hilus, where a dark shadow of tuberculous nodes was visible, a fairly opaque shadow of homogenous density extended outward into the lung for a considerable distance, gradually fading into the normal lung tissue.

The resulting infiltration was triangular in shape, its apex being near the axilla. Its lower margin was sharply defined by the interlobar fissure; the latter was thickened and the seat of a pleurisy, as it could usually be seen extending quite into the axilla beyond the limit of the infiltrated area. Sluka believed that it was a direct infection of the pulmonary tissue from the cascated lymph nodes at the hilus with a resulting infiltration of the lung. Sluka never found it before the age of two years in his series and their experience had been similar in the Roentgen examination of children. Perhaps the most remarkable fact in regard to these cases was that the infiltration did not remain constant in size or appearance. The Roentgen examinations made at intervals of one month might show at first a wide area of infiltration and at later examinations nothing might be left but the thickened interlobar fissure. The latter usually persisted for a long time as a thin sharp line running horizontally across the upper part of the right lung from the inner end of the fourth costosternal junction to the axilla. Such a sequence of infiltration and normal lung might be repeated several times and justified the appellation "recurring hilus infiltration," and its correspondence was found in the signs and symptoms of the patient. Children in whom this typical hilus involvement was found were usually brought to the physician on account of general debility, loss of weight, slight cough, or night sweats. The condition was found in children between the ages of two and eight years, but did not occur in infancy. Physical examination of the chest was usually negative unless the process had involved a considerable mass of lung tissue. This point was of the greatest importance since it emphasized the fact that in such debilitated children with positive von Pirquet test, *x*-ray examination was imperative. This was the more necessary since it had been shown that this lesion was in many cases a curable one, provided appropriate treatment was followed. The writers then reported two illustrative cases from a number coming under their observation and showed lantern slides of radiographs taken at different times during the progress of these cases. In closing they stated that the exact pathogenesis of these lesions was rather obscure, for corroboration by autopsy was impossible since the majority of the children recovered and those that went on to a fatal termination presented the picture of a general caseous involvement of the lung. The histories of many of the cases showed that before the onset of the condition the child had had either measles or pertussis, and the theory had been advanced that possibly there had been at this time not only a lowering of resistance to tuberculosis but also that local conditions in the bronchial lymph glands might be at fault. It was difficult to conceive of a true tuberculous infection coming and going in this fashion and the most plausible theory to account for it was that the underlying pathological process was one of an inflammatory exudate about the tuberculous hilus.

Some Factors Affecting the Incidence and Case Mortality Rate of Measles.—Dr. J. G. WILSON, Assistant Surgeon of the United States Public Health Service, read this paper, in which he stated that a study of the vital statistics of the various cities and states showed that at the present time the general mortality from measles was not nearly so high as it was when Holt placed the general mortality of measles at 4 to 6 per cent. and that of institutions at 10 to 35 per cent. In 1913, in New York City, the fatality rate per 1000 cases was 2.15 per cent. and even this was higher than that of any other city with a population of 500,000 or over. It would seem that we were well within the limits of conservatism if we placed the present case mortality of measles throughout the United States at less than 2 per cent. The assistant statistician of the Prudential Life Insurance Company, Frederick S. Crum, said that the most reliable international mortality statistics showed that on the average, in the countries in the temperate zone, more than 1 per cent. of all deaths were caused by measles. In the registration area of the United States the percentage which measles contributed to the total mortality during 1906 to 1910 was 0.71. The mortality was almost uniformly higher in institutions than in private practice. Dr. Wilson said he had had the opportunity of observing measles at the Immigration Station at Ellis Island and that, notwithstanding the unfavorable conditions offered by the steerage and the fact that patients were almost invariably exposed to cross infection during transportation from New York docks to the Immigration Station

at Ellis Island, the case mortality of measles at the Contagious Hospital at Ellis Island had averaged less than 10 per cent. from the time the hospital was opened in 1911 until the outbreak of the European war. Since that time measles had practically ceased until recently when the steerage from Rotterdam was again bringing the disease. In spite of the unfavorable conditions, the mortality at present was the lowest they had ever had, 8.5 per cent. The essayist exhibited charts showing the regularity of the recurrence of epidemics of measles in this country and in fifteen American cities. With few exceptions the disease showed a biennial periodicity. Various explanations had been advanced to account for this regular periodical recurrence. Muller and Crum believed that a measles outbreak in a community either actually attacked or immunized the whole susceptible population and that the off years following an epidemic simply represented the time required for a new susceptible generation to come into being. If this theory were correct, it would seem that in a continuously susceptible population, the yearly morbidity from measles would remain practically constant. It seemed probable that the immigrant population passing through Ellis Island was continuously susceptible to measles since it represented large handfuls of children of all ages picked more or less at random from widely separated communities of Europe. Notwithstanding this constancy of susceptible persons passing through Ellis Island the morbidity from measles had varied from 0.56 to 1.67 per 1000 immigrants for the last 15 years. A study of all the available data simply established the fact that measles epidemics showed a periodicity of recurrence and that this periodicity seemed to vary in different places. It was quite evident that the disease had no fixed mortality rate. There was probably as yet some undetermined factor entirely apart from age and unfavorable surroundings which entered into the situation and made the disease now a mild one with easy recovery and again a virulent one with a high incidence of complications and death. There was only one factor, overcrowding, which seemed to bear a causal relation to the incidence and fatality of measles and even this was incapable of explanation in its entirety. This factor had influenced the situation at Ellis Island and the same problem had been worked out by the health authorities in Glasgow where both the incidence and the fatality of the disease were shown to bear a direct relation to the number of rooms occupied by the family. Basing his statements on the results of his observation and examination of the histories of 2000 measles cases in the Contagious Hospital at Ellis Island, Dr. Wilson considered the three most important complicating conditions which influenced the course and termination of the individual case. These conditions were suppurative otitis media, bronchopneumonia, and cross infection. At Ellis Island it appeared that measles was four times as frequent as all other contagious diseases combined. Owing to the fact that many of their admissions had been exposed to more than one disease on board ship and in the transfer barges there were a certain number of cross infections, about 4.7 per cent. of the measles cases being complicated by some other contagious disease. This fact added materially to the measles mortality. In this series the mortality was 9.5 per cent. The mortality among the 36 cases contracting diphtheria was 66.6 per cent.; of those contracting scarlet fever 46.4 per cent. From a further study of this series of cases the writer concluded as follows: (1) Cross infection, especially that of diphtheria, was the most serious event that could occur in the course of measles. (2) Suppurative otitis media, although the most frequent complication of measles, was not of grave prognostic import when properly treated. (3) Bronchopneumonia complicated about 10 per cent. of all measles cases, being little influenced by weather conditions in the frequency of its occurrence or its fatality. (4) The fatality of measles complicated by bronchopneumonia was 58 per cent., but this fatality varied in an exceedingly erratic manner and without marked relation to the total case fatality of measles. (5) The incidence rate of bronchopneumonia as a complication rather than its case mortality appeared to be an index to the severity of any particular outbreak of measles.

Chloroma: A Report of Two Cases, Together with the Roentgenological Findings.—Drs. EVERETT W. GOULD and LEON T. LEWALD made this presentation. They stated that only a comparatively few cases of this condition had been reported and they therefore thought it advisable to place on record the following two cases which had appeared in the Pediatric Service of St.

Luke's Hospital. An analysis of the cases reported seemed to show that chloroma occurred more frequently in children than in adults and more frequently in males than in females. The chief clinical features which characterized the disease were exophthalmos, which was produced by a retrobulbar lymphoma; swellings of the temporal and occipital regions, due to the involvement of the cranial bones; enlargement of the spleen and lymphatic glands throughout the body, but especially in the cervical region, and a severe and progressive anemia causing weakness, fever, and emaciation. Hyperplasia of the bones of the skull undoubtedly began in the marrow of the cranial bones but soon involved the periosteum and the dura mater, forced the sutures apart, filled up various foramina of the skull, and by pressure upon the nerves which emerged from the brain through these openings might cause blindness, deafness, pain, or other symptoms referable to the nerves involved. While exophthalmos was the first symptom noted in a majority of the cases reported, in some cases there had been no exophthalmos. In the various reports nearly all the bones of the body had been cited as the seat of this change. The blood picture in chloroma varied greatly in the cases reported. The anemia was believed to be due to the rapid proliferation in the bone marrow of the leucoblastic tissues, resulting in the crowding out of the elements from which the red blood cells were derived. The anemia therefore depended upon the deficient production of red cells rather than upon any toxic destruction of them. The hyperplasia of the leucoblastic elements led to the frequent appearance in the blood stream of large numbers of white blood cells of various types and had led to the classification of this condition as a form of leucemia. In most of the reported cases this characteristic leucemic picture had been found at some time in the course of the disease, especially during the later stages. The predominating type might be any one of the normal or leucemic types of the leucocytes, or the hyperplasia of the parent cells might reach such a stage that the new forms did not reach the blood stream in such numbers as to give the picture of a leucemia. During the time that the cases herein reported were under observation the blood picture was never that of leucemia, but in these cases this time represented but a small part of the duration of the disease. The name "chloroma" was given to the disease because of the peculiar green color frequently seen in the tumors removed from the body, and which might also be found in any of the new growths, or even in a blood clot within the heart, though it was a more common characteristic of the hyperplasias of the bone marrow. Recent observations in regard to the histological characteristics of this disease showed that it did not belong to the lymphomata, carcinomata, or lymphosarcomata. Klein and Steinhaus perhaps first observed that the tumors of chloroma were largely composed of cells of leucoblastic origin. They found that neutrophile cells, especially myelocytes constituted a large part of the tumor mass. Large and small lymphocytes with eosinophile granules were frequently predominant, and they therefore classified the disease with the leucemias. Warthin showed that in his cases at least the tumors which involved the vertebrae and the prevertebral tissues were primary in the bone marrow spaces, that they infiltrated or grew through the lymphatics and blood vessels or broke through the bone, and secondarily involved the periosteum and surrounding tissues. Section showed that the normal marrow tissue was almost entirely replaced by cells of the large lymphocyte type, most of them showing eosinophile granulation. Transition forms of various kinds were numerous, but the whole vertebral tumor was made up of cells of leucoblastic origin with a scanty and delicate tissue reticulum, and with little evidence of new blood-vessel formation. Nodules of similar histological structure were found in various organs of the body, arising from intravascular proliferation and seeming to have little influence on surrounding tissues excepting by pressure and atrophy. There was little manifestation on the part of the organ involved of a reaction in the nature of a resisting proliferation of the tissue cells or the development of a reticulum and blood vessels. Of the two cases coming under their observation the writers stated that the first was a female child $3\frac{1}{2}$ years of age and the second a male child, 5 years of age. In neither instance was an autopsy obtained, but the Roentgen ray findings were fairly characteristic, especially in regard to the proliferation of bone tissue in the skull producing a separation of the suture lines. In the second case there

were characteristic changes in the long bones. The process seemed to be essentially a rarefaction and proliferation in the medullary cavities combined with a subperiosteal change lifting the periosteum over a variable distance from the surface of the shaft. The condition was distinguished from infantile scorbutus and rachitis by the absence of epiphyseal changes; from a myelomatous condition by the combination of the periosteal changes with the changes in the medullary cavity, and from sarcoma by the extent of the process. The change in the medullary portion of the bone appeared to be distinctly different from those of syphilis. The gross pathological changes in both of these cases were in exact accord with those described by Warthin. As far as the writers had been able to ascertain these were the first cases of chloroma in which the Roentgen ray findings had been recorded.

Dr. LEWALD exhibited lantern slides of the Roentgenograms of these patients. He said the radiograph of the first patient taken January 29, 1913, showed marked enlargement of the mediastinal lymph nodes with slight displacement of the trachea to the right. Another radiograph taken three days later confirmed the finding of enlargement of the mediastinal lymph nodes. Examination of the skull on February 5th showed a distinct separation of the coronal sutures, producing a wedge-shaped gap measuring one cm. at the vault. Radiographic examination of the head on February 12th confirmed the previous finding of separation of the coronal sutures and also showed a separation of the parietal sutures. Stereoscopic examination confirmed the findings of separation of the sutures of the skull including those of the occipitoparietal regions. The first radiographic examination of the second patient, made October 22, 1913, showed a distinct separation of the suture lines especially marked in the region of the coronal and the parietal sutures. The separation of the frontal suture measured about 2 cm. at the vertex. Examination of the chest showed an extensive involvement of the mediastinal lymph nodes. The diaphragm was pushed upwards on both sides, indicating a distinct enlargement of the liver and spleen. The bones of the upper extremities showed marked changes of a very peculiar type. The medullary portion of the long bones showed a peculiar mottling due to the rarefied areas. The periosteum was distinctly raised from the surface of the bone over the greater portion of the shaft. The peculiar combined involvement of the medullary cavity and the periosteum had not been observed in other bone lesions; from these findings a diagnosis of chloroma seemed justified, when taken in conjunction with the history of the case. Radiological examination of the lower extremities showed an involvement of the long bones exactly like that observed in the upper extremities.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held February 24, 1916.

DR. GEORGE W. KOSMAK IN THE CHAIR.

THIS program was arranged by the gynecological staff of the New York Polyclinic.

The Teaching of Gynecology to the Advanced Student. Dr. ARNOLD STURMDORF read this paper. He said that the pedagogics of gynecology and of post-graduate gynecology in particular presented intrinsic obstacles to both the teacher and the student that were not encountered in other specialized departments of medicine and surgery. Its diagnostic fundamentals demanded the cultivation of keen tactile perceptivity which could only be acquired among ample clinical facilities, such as were circumscribed by obvious prohibitive restrictions which limited the utility of the average gynecological patient for objective class demonstration; this created a relative paucity in opportunities for specialistic cultivation. The mechanistic empiricism that dominated the votaries of the established practice was slowly but surely merging into the realms of the obsolete. Surgical virtuosity alone no longer constituted a gynecologist; healed incisions and operative correction of purely objective deviations from hypothetical normals did not prove the cure, while the use of symptomatic nosology did not establish a diagnosis. They were formerly taught to see a passive retention wedge in the "perineal body" where they now recognized an active myodynamic deflector of intraabdominal pressure in the levator ani muscle. The time was passing when "endometritis" encompassed the beginning and end of

all uterine pathology, when "reflex neurosis" presented the shibboleth of its symptomatology, and "curettage" the slogan of its therapy. The student must be taught to see beyond his finger tips; an organism, not an organ, was the object of his study. He must learn to calculate in terms of "gonad and endocrine denominators;" to balance and correlate dynamic, biologic, and other factors in his clinical definitions. The student must be able to differentiate the gynecological manifestations of systemic disorders from systemic disturbances of gynecological origin. Individually, the post-graduate students were ardent and earnest men who sought knowledge at personal sacrifice; collectively, however, they presented a mental and technical heterodoxy that ranged from specialistic endowments down to an absolute lack in first principles; in the present status of post-graduate instruction, the teacher must adopt a course that ranged from the needs of those who could not locate a fundus uteri to those who sought the last word on the chemotaxis of ovular nidation. At the New York Polyclinic each of the six gynecological divisions conducted two clinics weekly, one operative and one ambulatory. The morning sessions were devoted to the details of surgical technique and the incidental study of operative findings in their anatomical, pathological, symptomatic, and diagnostic bearings. The ambulatory clinic, however, afforded opportunities for discussion and elucidation of advanced gynecological problems. In the ambulatory division of Dr. Sturmdorf's clinic he said he had adopted a course which met, as nearly as possible, the requirements of those seeking only a practical working knowledge, as well as those interested in the more academic phases of the subject. His class was divided into sections of twos. Sounds and specula were discarded and the previously established diagnoses and histories were withheld for the time. The students were supplied with the blank form on which their dictation of objective abnormalities were noted in strict topographic sequence as follows:

I. Topographic Sequence.

II. Objective Features.

III. Functions Involved.

IV. Symptoms Deduced.

V. Diagnosis.

Under one were the following: Vulva. Introitus. Vaginal Canal. Cervix Uteri—Outlines. Direction. Form Consistency. Fundus Uteri—Direction. Size. Horn. Consistency. Mobility. Adnexa—Situation. Form. Consistency. Mobility.

During the manual examination of the patient, any deficiency in method or tactile perception on the student's part was corrected. Based on these objective findings the functional disturbances were deducted and their incidental symptomatology postulated. In conclusion, Dr. Sturmdorf said that advanced gynecology was both an art and a science. The teacher could demonstrate its practice and elucidate its theories, but he could not impart aptitude and when all was said and done he had become convinced that advanced gynecologists were born and not made.

Supravaginal Hysterectomy by the Vaginal Route with a Report of Two Cases.—Dr. ADOLPH REICH presented this paper. He said that three conditions were recognized at present for which this operation was indicated: I. For the removal of the products of conception during the first four months in tuberculosis of the progressive type. II. In the presence of fibroids, or general fibrosis, of the uterus where the Wertheim-Schauta operation for prolapsus uteri could not be done on account of the large size of the uterus. III. For uterine hemorrhage which endangered life; in order to definitely check this source of loss of blood with the least trauma and least danger to life. Martin, in 1899, was the first who unintentionally performed this operation while doing a myomectomy through the posterior cul-de-sac. It was by chance that H. W. Freund came upon doing the operation extraperitoneally. His first case was in a primipara with a myoma the size of a child's head, and soft. The uterus was retroflexed. There were severe psychic disturbances, the patient being most rational during menstruation. On performing a posterior colpotomy the tumor proved to be a myoma which embraced the entire uterine wall. The upper portion of the fundus had to be removed leaving only a few centimeters above the internal os. The intended myomectomy resulted in a supravaginal hysterectomy, but the stump was not covered with peritoneum. His second case was a patient who had given birth to three children. She was forty years old. The uterus was

very large and the body with its adnexa was amputated in the usual classical manner, covering the cervical stump with the bladder. In July, 1908, H. v. Bardeleben decided to cut an elliptical portion out of the tip of the fundus, taking away most of the placenta site, and leaving just a few centimeters of tissue above the internal os, and closing the fundus with five or six interrupted sutures fastened to the bladder on the posterior surface of the cervix. The operation was finished *lege artis*. He based his indications on the observation of the fact that ordinary abortion with or without sterilization produced, in those cases which were followed for a period of sixteen months, the mortality was from 8 to 53 per cent., while with the amputation among the same class of cases only 5.6 per cent. died during the same period. In the Wertheim-Schauta operation, the uterus had to act as a supporting wedge in the urogenital diaphragma; the success of the operation did not, therefore, depend upon the correct technique of the fixation only but also on the size of the uterus. Stoschel stated that under ordinary conditions he never had found the uterus too large, and in cases of fibroids he preferred to do a hysterectomy and utilize the broad ligaments as the future support for the bladder and vagina. This later procedure undoubtedly prolonged the operation to a considerable extent. The Pfannenstiel wedge resection was frequently accompanied by oozing of blood, necessitating drainage in a number of cases; secondary hysterectomy had to be resorted to in order to check the hemorrhage. Several had reported good results, with preservation of menstruation, by leaving a few centimeters of the endometrium above the internal os in young women who, after all kinds of treatment, bled persistently and were doomed to hysterectomy, no matter what the cause might be, whether myoma, metritis, arteriosclerosis, neurosis, etc. They all knew that in those severe cases of patients who hardly had time to recover from the loss of blood from menstruation to menstruation, hysterectomy might be absolutely indicated.

Statistics were not at all conclusive. Without considering the gross complaints elicited voluntarily by the patient, or by their direct questioning, there was a fine psychic and physical process connected with menstruation which they could not elicit by their studies; of which perhaps the women themselves were not conscious. A woman without her menstruation was not considered as a full value either by men or women, and no one knew whether such a young woman developed in a different manner from those who were in possession of this function. It was therefore best to cure the woman of the excessive bleeding with preservation of her menstruation. This was best accomplished by leaving about two cm. of the fundus above the os. In a case of procidentia a "T" shaped incision was made into the anterior vaginal wall; then separating the bladder from the uterus and vagina freely, the uterovesical fold was opened and the fundus was pulled down into the vagina and, the bladder being held up with a towel, the uterosacral ligaments were plicated, leaving the last suture long. A pair of blunt forceps was pushed through the broad ligaments to catch the last suture attached to the uterosacral ligaments and then bringing them out along both sides of the cervix, the bladder peritoneum was fastened to the postuterine wall at the level of the internal os. The round ligament and tubes were then tied off and if necessary the ovaries and tubes could be entirely removed. The broad ligament was pushed down and the uterine artery tied along the side of the uterus and as much of the fundus cut off as would make it fit the gap comfortably. The round and ileopelvic ligaments were sutured to the stump of the fundus, the vaginal flaps trimmed and sutured to the vagina along the entire anterior wall of the uterus. The two sutures that held the uterosacral ligament were tied and the operation was concluded by a good perineorrhaphy.

Dr. JOHN VAN DOREN YOUNG had examined the cases reported by Dr. Reich; the patients complained of no pain and the results he believed were all that could be desired.

The Care of Abdominal Surgical Cases.—Dr. BROOKS H. WELLS said that when he began his service at the New York Polyclinic in 1885, they used the old cumbersome methods, drastic purging, elaborate preparation of the patient and the site of operation, antiseptics instead of asepsis, drainage when in doubt—and in nearly all cases they were in doubt—a crude technique with its necessarily high mortality and morbidity, the so-

called stimulation of the patient by strychnia and digitalis, and enforced immobility of the patient with many weeks in bed. A gradual evolution had led to the reversal of most of these conditions and to an increasing simplicity in the management of abdominal cases until during the last few years they had treated them substantially as he then described, with a great fall in the mortality and morbidity, a great lessening of postoperative pain and discomfort, and, practically entire absence of postoperative hernia. With better training for the younger surgeons, with increased knowledge of the simplified and perfected technique which would eventually prevail, surgical morbidity—and with it, mortality—from purely surgical causes should drop almost to the vanishing point. When patients were admitted to the hospital, and if operation was considered necessary, the preparation for this was very simple and consisted of a mild laxative on the morning of the day preceding the operation, followed by an enema the evening before, together with the preparation of the skin. Severe purging was avoided, as it increased the tendency to bowel distention and the formation of gas; this was a great source of discomfort to the patient and increased postoperative intestinal atony, nausea, and vomiting. Only rarely were patients held in the hospital for more than twenty-four hours before going to the surgeon. Usually the evening before operation the abdomen was shaved and scrubbed with tincture of green soap and warm water, rubbed on with a piece of clean gauze. The soapy water was carefully and completely washed off and the skin dried with alcohol and covered with a light dressing of sterile gauze. When the gauze was removed before operation, the dry skin was painted with tincture of iodine, three and a half per cent. A moderate Trendelenburg position was used in nearly all cases. As was also an intermuscular or the suprapubic transverse incision; this incision having been found to give most satisfactory results, with great freedom from hernia and an inconspicuous scar. Its greatest fault was the liability to the formation of the hematoma from imperfect or careless hemostasis. Gentleness of manipulation was strongly urged; no rough handling or sponging of peritoneal surfaces was allowed. Vessels were ligated before being divided, and clamps were never applied except to tissues that were to be removed; this was an important means of avoiding thrombosis and consequent embolism. Great care was taken to repair all torn or denuded peritoneal surfaces. Van Horn and Sawtell catgut was used in the peritoneal cavity, doubled where greater strength was necessary. No. 0 or 1 chromic gut was used for intestinal work; celluloid linen was discarded as dangerous and liable to produce late complications. Abdominal incisions were closed in layers with No. 1 plain catgut for the peritoneum, No. 2 ten-day chromic gut for fascia, and No. 0 or 1 plain catgut for the skin. Where there seemed danger of wound infection through-and-through silkworm gut sutures were used in median incisions in addition to the catgut layer sutures. Before the patient was taken off the table, she was given a hypodermic of atropine sulphate, gr. 1-120, followed in a few minutes by a hypodermic of eserine salicylate, gr. 1-50. The eserine could be repeated at six hour intervals as might be needed. It was found to have a positive effect in relieving postoperative pain, and in helping to blot out the recollection of pain; it lessened the nausea, promoted intestinal peristalsis, and lessened the shock. Morphia was needed to control the pain in only one case in four. Eserine should not be used in larger doses than 1-50 of a grain. Where there was actual obstruction eserine was a dangerous agent. After a prolonged anesthesia the stomach was washed out at the end of the operation. If there was vomiting, water with a little sodium bicarbonate was given freely by the mouth and, when the condition would permit, the head and shoulders were raised. To relieve shock, to supply fluids, and to control thirst, a half pint of pure water was given by rectum every four hours until the bowels moved or until the patient could take fluids freely by the mouth. The bowels moved spontaneously as a rule; if they did not, castor oil was given on the third or fourth day. Early feeding was considered quite important. After operation the patient was allowed from the first to turn in bed or be moved by the nurse. On the fourth day, unless there was some contraindication, she was lifted out of the bed into a chair for a short time. Early mobility encouraged the patient, lessened the nausea, promoted the early return of the appetite, increased peristalsis, made the bowel movements easier,

improved the respiration, lessened the tendency to pulmonary complications, prevented loss of muscle tone, and greatly facilitated a rapid convalescence. When patients were sent home early from the hospital, they should be kept in bed most of the day for another two weeks or longer. With these precautions they had not seen the neurasthenic conditions or other ill results that had been said to follow early rising.

Ectopic Gestation.—Dr. LOUIS J. LADINSKI presented this communication, giving only a short abstract of the papers published by him in 1907 and 1912, in which he reported 110 and 200 operative cases respectively. Since that time he had operated upon 45 additional cases. He said the signs and symptoms of ectopic gestation might be divided into two groups, those of the ruptured and of the unruptured. The diagnostic signs and symptoms in the unruptured type were amenorrhea, or some irregularity of menstruation, a feeling on the part of the patient that she was pregnant, pain which was sharp, lancinating, and paroxysmal in character not only referred to the affected side but particularly to the ovarian region, bleeding from the uterus usually beginning about the sixth or seventh week, enlargement of the uterus, its consistency, however, being that of the non-pregnant organ. The most reliable sign of uterine pregnancy was found in the elastic area in the median line of the anterior wall of the body of the uterus, above the junction of the body with the cervix. In tubal pregnancy, while the uterus was enlarged, the elastic area in the anterior wall was never present except where the disintegration of the decidua did not take place before the removal of the gravid tube when there was an absence of bleeding and the decidua was subsequently expelled in the form of a cast of the uterus. In this series of 245 cases in all there had been but three decidual uterine casts. A further sign was the presence of a distended tube on one side. Two negative signs of great importance were the exclusion of uterine pregnancy and the absence of elevation of temperature. The leucocyte count and the hemoglobin test were of no value in the unruptured variety; after rupture there might be an increased leucocyte count and reduced hemoglobin percentage. It was a fairly safe rule to think of ectopic gestation in every patient who had had amenorrhea which was followed by irregular bleeding and pain on one side. In ruptured tubal pregnancy the additional local and constitutional signs of internal hemorrhage attendant on rupture were pathognomonic of the condition. The symptoms caused by rupture would depend for their severity on the extent of the rupture and displacement of the ovum and the amount of internal hemorrhage and would range and merge from a state of syncope to that of shock, collapse, and, occasionally, unconsciousness. The anemia, blanching of the mucous membranes, thirst, air-hunger, shallow and rapid respiration, feeble pulse, and subnormal temperature varied according to the degree of the hemorrhage and the resisting power of the patient. Locally the abdomen might be distended and tender, and palpation would elicit a fluid wave. Bimanual examination would, as a rule, reveal a soft boggy tumor on one side or the other. When the gravid contents had become entirely detached and floated in the peritoneal cavity, or when perforation had taken place during the early months of pregnancy, especially in the isthmal type, no localized pelvic tumor would be palpable, and the only evidence of rupture would be the presence of free fluid in the pelvic and abdominal cavities. Exploratory vaginal section for diagnostic purposes, except in pelvic hematocele and hematoma, was absolutely uncalled for in ordinary tubal pregnancies and was an unnecessary procedure. The only rational treatment of ectopic pregnancy was operative. It was undeniably a fact that both the mortality and the morbidity of this disease were greatly increased by delayed operation. In this series of 245 operations to date, there were four deaths and these had been reported in detail in his previous report. In one of these, death followed a simple salpingectomy in an unruptured tubal pregnancy; the other three were undoubtedly due to a delayed operation. Hemorrhage from a ruptured tube must be regarded in the same light as hemorrhage from any other source and should be checked as quickly as possible regardless of the severity of the shock. It was Dr. Ladinski's belief, justified by the results obtained in the cases of extreme collapse, that if the operation was performed with ordinary skill and rapidity, the additional shock would be so slight that it could not possibly be held responsible for a single death, especially if infusion or transfusion be resorted to as soon as

the abdomen was opened. Every case of profound shock operated upon by him recovered; no case was refused the benefit of operation as long as there was a cardiac beat. The technique employed was practically identical with that employed by him in his first operation twenty-one years ago. He could not subscribe to the doctrine of deferring operation and trusting to chance, the inevitable result of which was to rapidly diminish the margin of reserve strength of the patient. He could not see the wisdom of the rule of watching the patient to see if she improved or lost ground with the view of waiting without operation when the patient was improving, and operating if she grew worse. If the patient's condition improved without operation, there could be no question that she would be better off because of the operation; but to wait until the patient grew worse meant the unnecessary loss of very valuable and precious moments and possibly the sacrifice of life. He had no hesitancy in saying that the operation for tubal pregnancy was attended by no greater surgical risk than opening the abdomen for other conditions, and shock was assuredly no contraindication to the immediate operation for ruptured tubal pregnancy.

Sacral Suspension of the Uterus.—Dr. JOHN VAN DOREN YOUNG presented this paper, which was illustrated by lantern slides. (See MEDICAL RECORD, December 4, 1915, page 980.)

The Nerve Supply of the Lower Abdominal Wall as Related to the Pfannenstiel Incision.—Dr. DAVID W. TOVEY read this paper. He said that the nerves with which they were concerned in the Pfannenstiel incision were the anterior divisions of the twelfth dorsal and the hypogastric branch of the first lumbar. After describing in detail the course of each of these nerves, he said that in the Pfannenstiel incision, after the aponeurosis had been separated from the muscle and the linea alba divided and the upper flap retracted, two or sometimes four large nerves could be seen coming up from the recti about an inch from the median line and piercing the anterior fascia. These were the anterior divisions of the twelfth dorsal nerve. They were often half as thick as a match, double, and accompanied by blood vessels. They should not be cut, as in retracting the upper flap they could be drawn out sufficiently in nearly all cases. If scissors were used, these nerves might be taken for connective tissue and cut. In the writer's opinion this would account for some of the cases of hernia which had been reported as following a Pfannenstiel incision. If looked for, these nerves could be seen in every operation. The upper part of the anterior division of the twelfth dorsal nerve was not seen and, if care was taken to split the oblique muscles in the direction of their fibers, there was no danger of cutting it even with the extended incision used in large tumors. When a very large opening was required, the incision through the skin could be made from one spine of the ilium to the other. The incision through the aponeurosis was then prolonged over the lateral edge of the rectus muscle and the oblique muscles were split along the lines of their fibers, if necessary, out to the iliac spine. The detachment of the aponeurosis from the recti could be effected upward as far as the umbilicus and downward as far as the symphysis, the pyramidal muscles remaining upon the flap of the aponeurosis. The recti muscles were separated and the peritoneum severed in the midline. This made a very large opening suitable for the removal of the largest tumors and made it easy to operate deep in the pelvis. For a smaller opening, the incision was made in the pubic fold which occurred in all women at all fat. It should be made almost straight and with only the slightest curve, not crescent-shaped, as it was often described. In young women when a small incision was all that was needed, the skin incision could be made below the line of the pubic hair, the skin and fat were then pushed up and the aponeurosis divided at a higher level. There was no danger to the bladder if the peritoneal incision was started high, and in cutting toward the pubes one could tell when he was near the bladder by the thickening of the tissue and the little bleeding points encountered. It made little difference in medium-sized incisions whether the pyramidalis were left attached to the rectus sheath where they acted as tensors of the fascia, or were separated and left on the recti, or whether the peritoneum was entered at the outer side or between them. Hemostasis should be carefully looked for before closing the incision. At the Polyclinic Hospital they had used this incision even for large tumors and in infected cases and found that it healed with less danger of hernia than the vertical incision.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

OKLAHOMA STATE BOARD OF MEDICAL EXAMINERS.

January 11 and 12, 1916

(Concluded from page 676.)

OBSTETRICS AND GYNECOLOGY.

1. Give differential diagnosis of pregnancy at the sixth month.
2. What is ophthalmia neonatorum? Give prophylactic treatment of same.
3. What is pituitrin? How and for what do you use it in obstetrics? What are your methods of controlling hemorrhage in accouchement?
4. Give your treatment of puerperal infection.
5. Give your management of a face presentation.
- 6-7. Give in full, etiology, diagnosis, treatment, and prognosis of gonorrhea in women.
8. Under what conditions is uterine curettage indicated, and under what conditions contraindicated?
9. Give diagnosis and treatment of carcinoma of the uterus; prognosis of same.
10. Name the arteries and describe the circulation of the internal generative organs of the female.

SURGERY.

1. Give symptomatology, differential diagnosis, and treatment of abscess of brain.
2. Give etiology and treatment of acute otitis media purulenta.
3. Give technique of operation for drainage of mastoid abscess.
4. Give treatment for compound fracture of tibia.
5. Describe two well-known dressings applicable to fracture of clavicle.
6. Describe in detail the various movements in reducing iliac dislocation of head of femur by manipulation.
7. Give symptomatology, diagnosis, and treatment of acute appendicitis.
8. Give symptomatology, diagnosis, and treatment of recent tuberculosis of the knee. Give treatment after abscess formation.
9. How would you treat burns of the first, second, and third degree?
10. In case of anterior poliomyelitis, paralysis of what muscles result in talipes varus? Give treatment.

TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. Define civil and criminal malpractice.
2. Give two or more tests of personal identity.
3. In a suspected case of criminal abortion how would you determine whether pregnancy had existed?
4. What are the postmortem findings in drowning?
5. Define rape, and tell what three conditions are necessary to be produced by medical testimony to prove rape.
6. What is the first thing you would do in being called to a case of poisoning?
7. Name two reliable emetics; give dosage.
8. Give symptoms of cocaine poisoning; fatal quantity?
9. Distinguish between opium poisoning and acute alcoholism.
10. Describe physiological antidote and chemical antidote and give an example of each.

HYGIENE.

1. How is malaria transmitted? How may it be prevented?
2. What disease carriers are propagated in and about stables?
3. State the best means of disposing of and disinfecting sputum.
4. How long does a diphtheria patient remain infective? How can the termination of this period be determined?
5. What is *Trichina spiralis*? Where most commonly found?

ANSWERS.

OBSTETRICS AND GYNECOLOGY.

1. Pregnancy at the sixth month is diagnosed by the presence of the fetal heart sounds and active and passive fetal movements. In no other condition are these present.
2. Ophthalmia neonatorum is a conjunctivitis of the

newborn caused by the gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms*.—Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis*.—Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth.

3. *Pituitrin* is an extract made from the posterior lobe of the pituitary gland, and is used for the relief of uterine inertia. It is best administered intramuscularly in the gluteal region in doses of 1 c.c., which may be given two or three times at intervals of half an hour. Its use is not without danger.

The hemorrhages that may affect a parturient woman are those caused by: (1) Placenta prævia; (2) premature separation of a normally situated placenta; (3) relaxation of the uterus; (4) laceration of the cervix; (5) rupture or inversion of the uterus; (6) retained secundines; (7) displaced thrombi; (8) fibroid tumors; (9) hypertrophied decidua; (10) carcinoma.

"In the presence of actual hemorrhage the treatment varies according as the placenta is still within the uterus or has already been expelled. In the former case the uterus should at once be grasped through the abdominal wall and firmly kneaded. If firm contractions come on all is well, but if the hemorrhage continues and the uterus relaxes as soon as the kneading is stopped the placenta should be expressed by Credé's method; and if this cannot be accomplished and the patient's condition is alarming, manual removal may become necessary. . . . If the hemorrhage does not cease after the delivery of the placenta, the cause should be ascertained and suitable treatment instituted. Tears should be located and their edges brought together by sutures. On the other hand, if the hemorrhage is the result of the retention of placental tissue, the carefully disinfected hand should be carried up into the uterus in order to seek for and remove the retained cotyledon. Under such circumstances the hand acts as a most efficient irritator, causing the uterus to contract energetically. After separating the retained portion of the placenta the hand should not be withdrawn at once, but should be allowed to recede gradually as it is forced down by the contraction of the fundus. If the hemorrhage is due to atony the uterus should be vigorously kneaded and from 40 to 60 minims of ergot or of ergotol administered hypodermically. . . . If these measures are not attended with the desired result a very hot intrauterine douche of several liters of sterile salt solution should be employed. . . . If the hemorrhage persists in spite of the douche our only hope of controlling it is by packing the uterus tightly with sterile gauze. Before resorting to the use of the pack it is always advisable to palpate the interior of the uterus, as occasionally a portion of the placenta may have been retained, even though immediately after expulsion the organ may have apparently been entire." (Williams' *Obstetrics*.)

In case of *post-partum hemorrhage*: Grasp the uterus at once, through the abdominal wall, and massage it firmly. Anything in the uterus should at once be cleaned out. Pass one hand into the uterus, and with the other, on the outside make firm pressure. A hypodermic of ergotin or ergot can be given by an assistant. An intrauterine douche of hot sterilized water (about 115° F.) may be given. Sometimes a very thorough packing and plugging with gauze of uterus and vagina may be necessary. Whatever is done must be done promptly; and everything likely to be needed for this emergency should be prepared beforehand in every labor.

4. "The treatment of *puerperal sepsis* is both local and general. Locally a thorough disinfection of the whole genital canal is called for in every case. It may appear unnecessary, and may prove, on actual experience, to be even harmful, but no one can tell beforehand how necessary this procedure is. In the vast majority of cases it is productive of the greatest good. It is only occasionally useless, and very rarely actually harmful. It should precede all other treatment for puerperal infection. The method of disinfecting the genital canal may be described as follows: A double tenaculum, a large, dull curette, a placental forceps, and an intrauterine catheter are boiled for fifteen minutes. The operator disinfects his hands and arms and wears

sterile gloves. The patient is placed in the dorsal posture across the bed, with her buttocks resting on a rubber pad. The external genitalia and the vagina are scrubbed with tincture of green soap and pledgets of cotton; the vagina is douched with a sublimate solution, 1:2000. The operator then seizes the anterior lip of the cervix with a tenaculum. An intrauterine douche of sterile water, at least a quart, is administered. Then, with the placental forceps, and, if necessary, with a dull curette, the uterine walls are gone over thoroughly but lightly in all directions, six to twelve times, until nothing is brought away but bright blood. A second intrauterine douche concludes the treatment. If the womb is flabby and large, with a tendency to flexion, so that the drainage of the uterine cavity is not good, it is advisable to pack it with iodoform or sterile gauze. In addition to cleansing the uterine cavity, false membranes or areas of inflammation and localized infection on the cervix or vagina should be treated by the application of a solution of nitrate of silver, a dram to the ounce. It may be necessary to repeat the intrauterine douches several times—in fact, several times a day for many days; in this case plain sterile water only should be used. The general treatment is stimulating. The patient should have as much food of an easily digestible character, chiefly milk, as she can assimilate, and as much alcohol as she can consume without showing the physiological effects of it. Digitalis is useful as long as the pulse is above 110. Strychnine may be combined with it in suitable cases. To tide the patient over emergencies, carbonate of ammonium in large doses, by the bowel, and nitroglycerin, hypodermatically, may be required. Inhalations of oxygen may be of service. Absolute rest and freedom from all disturbances, mental and physical, must be insisted upon, and the patient should be given the best nursing that the family can afford." (Hirst's *Obstetrics*.)

5. *Management of face presentation*: If the chin is presenting anteriorly, expectant treatment may suffice; but care must be taken to observe that the chin does not rotate backward. Spontaneous version may occur and the presentation become a vertex one. Failing this, or as a means of favoring this, postural treatment, such as Walcher's position, has been recommended. If, in spite of this, engagement has not occurred, cephalic version is indicated, care being taken not to rupture the membranes. If this is not successful, podalic version should be tried. If, after all these manipulations, the child is still alive and the head is engaged, symphyseotomy is indicated; if the child is dead, craniotomy should be performed.

6 and 7. *GONORRHEA: Etiology*.—The gonococcus of Neisser. *Symptoms*.—Pain and burning in the vulva; pain and burning on micturition; dyspareunia; yellowish or greenish discharge, in which the gonococcus can be found; the vagina is hot, red, swollen, and tender. *Possible results*.—Cystitis, urethritis, vulvitis, endometritis, salpingitis, septic peritonitis, sterility, condylomata of vulva, abscess of Bartholin's glands. *Diagnosis* is made from the symptoms, particularly from finding the gonococcus in the discharge. It is so serious on account of the possible results enumerated above; it often leads to chronic invalidism, and may be the cause of death. *Treatment*.—Rest, if possible in bed; freedom from alcoholic or sexual excitement; a mild and unirritating diet; salines and diuretics; plenty of water to drink; a warm sitz bath; douching of vagina with about a gallon of a 1:5000 bichloride solution, or of borax (1 dram to the quart), or of potassium permanganate (1 per cent. solution); the douche is to be taken in the recumbent position.

8. *Curettage is indicated*: (1) For removal of placental debris, (2) in hemorrhagic endometritis, (3) in some forms of dysmenorrhea (membranous), (4) for diagnostic purposes, (5) in some cases of puerperal sepsis, (6) sometimes to check hemorrhage due to fibroids. *Contraindications*: (1) The least suspicion of even the possibility of pregnancy, (2) menstruation, (3) acute endometritis, (4) malignant disease of the uterus or vagina, (5) acute pelvic inflammation.

9. *Carcinoma of the uterus is diagnosed* by the history, symptoms, physical signs, and microscopic examination. It is a disease of advancing years, and generally occurs after the menopause; nulliparæ and multiparæ are equally liable. The chief symptoms are hemorrhage and discharge with an offensive odor, pain, and cachexia. The cervix is soft, the uterus enlarged, and tender. The uterus must be curetted, and the scrapings examined by the microscope.—*Treatment* consists in thorough removal at the earliest possible moment.

This is often impracticable, because of the delay in seeking advice. *Prognosis* depends upon the time at which the diagnosis is made; in cases unsuitable for operation life is rarely prolonged beyond from three or four to twelve or eighteen months.

10. "The blood supply of the uterus is derived from the uterine artery, a branch of the internal iliac, and the ovarian, from the abdominal aorta. The uterine artery reaches the uterus at a point opposite the supravaginal portion of the cervix and crosses in front of the ureter at a distance of $\frac{1}{4}$ inch from the cervix. It then bends upward and runs close beside the body of the uterus, between the folds of the broad ligament, giving off a number of branches which supply the uterine wall, and at the angle of the uterus anastomoses with the ovarian artery. The spiral course of the uterine artery is for the evident purpose of allowing for the increased size of the uterus during pregnancy without causing tension of the vessels. The veins of the uterus take their origin in the venules of the mucosa and muscularis. The branches which traverse the muscularis are by far the most important. In the pregnant uterus they undergo enormous development and form the uterine sinuses. The uterine veins terminate in the venous plexuses of the broad ligament and anastomose with those surrounding the base of the bladder, the vagina, and rectum. The ovary is supplied by the ovarian branches of the abdominal aorta, which enter the pelvis in a fold of the broad ligament, and thence continue to the attached border or hilum of the ovary. They anastomose with the uterine arteries. The veins form a plexus near the ovary and empty into the ovarian vein, which in turn empties into the renal vein on the left side and into the inferior vena cava on the right. The blood supply of the Fallopian tubes is derived from the branches of the ovarian arteries which run along the lower border in the folds of the mesosalpinx. The veins communicate with the venous plexus of the broad ligament." (Campbell's *Surgical Anatomy*.)

SURGERY

1. *ABSCCESS OF THE BRAIN. Symptoms*: "The symptoms in traumatic cases are acute, and, as there is usually diffuse meningitis, there is intense pain, fever, and rigors, coma quickly supervening. In the more common chronic cases the symptoms are often vague in the early stages, but when well marked consist in signs of intracranial pressure. 1. The headache and tenderness are severe and localized to the site of the abscess. 2. The temperature is subnormal, unless there is associated meningitis. 3. The pulse is markedly slowed, even down to 30 or 40. 4. The patient is quite intelligent, but cerebation is very slow; vomiting and optic neuritis are usually present. 5. Motor symptoms may occur if the abscess is in the anterior part of the temporo-sphenoidal lobe, either irritative or paralytic. If the cerebellum is affected, there is giddiness both while walking and lying down, together with weakness of the hand-grip and increase in the knee-jerk on the side affected. Lateral nystagmus often occurs.

"*Diagnosis*: From meningitis, by the fact that in meningitis there is fever, great restlessness, delirium, photophobia, pain and spasm in the muscles, especially at the back of the neck. An extradural abscess is always accompanied by fever. In lateral sinus thrombosis there are rigors and profuse sweats, and there may be a hard tender cord in the situation of the internal jugular vein. Chronic abscess and tumor are often indistinguishable in their symptoms, but the presence of chronic otitis media suggests abscess.

"*Treatment*: The abscess must be opened as soon as possible. Unfortunately, many cases are only diagnosable when it is too late for evacuation to produce a cure. As cerebellar abscess is more common, it is as well to explore the cerebellum first, unless focal symptoms point to the temporo-sphenoidal lobe as the site. A flap is turned down and a piece of bone removed with a trephine. The dura is then incised and the abscess punctured with a trocar and cannula or sinus forceps. These should be passed in various directions till the pus is found, and then the opening must be enlarged, the pus gently washed out, and a drain left in for several days. For a temporo-sphenoidal abscess the trephine opening should be made $\frac{1}{4}$ inch above the posterior root of the zygoma, and directly above the posterior border of the bony meatus; for a cerebellar abscess, $1\frac{1}{2}$ inches behind the center of the external auditory meatus and 1 inch below Reid's base line. In most cases the mastoid antrum should be first explored; by removing the bone behind it the lateral sinus can

be exposed, and by working above or below it the cerebrum and cerebellum can be explored."—(*Aids to Surgery*).

2. *Acute purulent otitis media* is caused by pharyngitis, tonsillitis, diphtheria, scarlet fever and other fevers, adenoids, and the passage of pathogenic germs from the nasopharynx to the middle ear. *Treatment*: "Dry heat allays the pain. Warmed water or warmed carbolic acid solution (1:40) may be used. Inflation, aspirations, etc., should be avoided. If the nares are filled with tough secretions, a spray of Dobell's solution may be used. If the pain continues over six hours in a child or over twelve hours in an adult without spontaneous perforation of the tympanic membrane, paracentesis of that structure should be performed. The concha and meatus should be smeared with petrolatum to avoid chapping, and the secretions should be gently mopped off as they appear. Under this treatment the ear usually returns to normal in two to three weeks." (*Pocket Cyclopaedia of Medicine and Surgery*.)

3. *For drainage of mastoid abscess*: "A curved incision is made over the mastoid about a quarter of an inch behind and parallel with, the attachment of the auricle. The periosteum is detached and the auricle turned forward until the posterior and superior walls of the osseous meatus are exposed. If a sinus is found it should be enlarged by means of a gouge, as it almost certainly communicates with the antrum. If there is no sinus, the gouge should be applied in the supra-meatal triangle, which is bounded above by the posterior root of the zygoma, below by the upper and posterior segment of the bony external meatus, and behind by an imaginary line joining these. The instrument should be directed forward and inward to avoid injuring the sigmoid sinus. If the opening be carried too high, the middle fossa of the skull may be opened. The antrum and cells having been freely opened up, the cavity is irrigated and packed with iodoform gauze, which is renewed daily till the discharge ceases, and the cavity is filled in by granulation." (Thomson and Miles' *Surgery*.)

4. "In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, and limb shaved, and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle, and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced, after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought accurately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage tube is inserted, and, if need be, counter-openings are made; the external wound is closed or not, according to circumstances, and dressed and suitable splints are then applied. Under such a régime the majority of cases do well. Immovable apparatus may be used after a time, windows being left in the plaster casing to allow wounds to be dressed."—(Rose and Carless' *Manual of Surgery*.)

5. *Sayre's method for fractured clavicle*: "Sayre's dressing consists of two strips of adhesive plaster three and a half inches wide and two yards in length. The first strip is looped around the arm just below the axillary margin and is pinned or sewed with the loop sufficiently open not to constrict the arm. The arm is then drawn downward and backward until the clavicular portion of the pectoralis major muscle is put sufficiently upon the stretch to overcome the action of the sternocleidomastoid muscle, and in this way draws the sternal fragment of the clavicle down to its place. The strip of plaster is then carried completely around the body and pinned or stitched to itself on the back. The second strip is next applied, commencing on the front of the shoulder of the sound side; thence it is carried over the top of the shoulder diagonally across the back, under

the elbow, diagonally across the front of the chest to the point of starting, where it is secured by pinning or sewing. A slit is made in this strip to receive the point of the elbow. Before the elbow is secured by the plaster it should be pressed well forward and inward."—(Wharton's *Minor Surgery and Bandaging*.)

Another method is to place a wedge-shaped pad in the axilla, raise the elbow by a sling, and bandage the arm to the side, with the hand placed on the opposite side of the chest.

6. In posterior luxation of the hip joint the patient should be placed on a mattress on the floor and then be anesthetized. The leg is then to be flexed on the thigh, and the thigh flexed on the abdomen; adduction is to be increased so that the knee is beyond the middle line of the body; then abduct, freely circumduct outward, and finally extend the limb so that it is parallel with the other.

7. *Catarrhal appendicitis with localized plastic peritonitis* begins suddenly with pain about the umbilicus or right iliac fossa, vomiting, constipation, and slight fever. There is some tenderness at or about McBurney's point. A swelling, due to matted coils of intestine, may be felt, and there is always rigidity of the muscles in the right iliac fossa. There may be pain at the end of micturition, due to stretching of inflamed peritoneum as the bladder is emptied. The attack usually subsides in three or four days, leaving adhesions.

Appendicitis with a localized abscess begins in the same way, but one or more of the signs—pain, vomiting, tenderness, and temperature—is more severe. A well-marked swelling is usually present, and the pulse steadily increases in frequency. There is also a steadily-increasing leucocytosis. A persistently high temperature, or a subnormal temperature with an increasing pulse-rate, are strong indications as to the presence of pus.

Diagnosis.—The cardinal signs are pain and tenderness in the right iliac fossa, vomiting and constipation, with some rise of temperature. If a swelling and localized rigidity are present, there can be no doubt.

Treatment.—The cases, as regards treatment during an attack, fall into two groups: (1) Where there is only plastic peritonitis; (2) where there is suppuration. In the first group the patient should be kept at rest, with hot fomentations to relieve the pain. Fluid diet should be given, and the patient not disturbed for several days by purgatives or enemata. On no account should morphia be given, as it masks the symptoms of the onset of suppuration. Where pus is present or suspected, the abdomen should be opened over the swelling, and in most cases it will be found that there are adhesions to the anterior abdominal wall, shutting off the abscess cavity from the rest of the abdomen. A finger should be gently inserted to feel for and remove a concretion or the appendix; but no prolonged search should be made for the appendix for fear of breaking down the adhesions. A large rubber drainage-tube should be inserted, and the cavity will soon become clean and heal by granulation. If, when the abdomen is opened, no adhesions to the anterior abdominal wall are found, the cavity should be protected with gauze packing. The abscess will then be found among a mass of matted omentum and intestine, and can be opened by gently separating them. A drainage-tube is inserted, and the gauze packing is left in for three days. By that time firm adhesions have formed and the peritoneal cavity is safe from infection. When general peritonitis is present, the abdomen must be opened and drained and the appendix removed; but these cases are almost always fatal. In any case in which the symptoms are excessive, especially with a rapidly increasing pulse-rate, an operation should be done, as this gives the only chance in cases where there is suppuration without adhesions, especially in those cases due to perforation or gangrene. —(From *Aids to Surgery*.)

8. In *tuberculosis of the knee* there will be slight pain, limping, some limitation of motion, swelling, the joint is spindle-shaped and the skin over it is white; palpation imparts a doughy sensation; night cries may be noticed, the knee is held in a position of flexion. Diagnosis is aided by the x-ray, an examination of the aspirated fluid, and (possibly) the tuberculin test. Treatment consists of immobilization of the joint with plaster of Paris or a splint; injections of iodoform are useful; erosion or excision may be indicated. Constitutional treatment includes fresh air, good food, sunshine, and tonics.

9. *Treatment of burns*.—General: If carbonic-oxide

poisoning is present, artificial respiration and administration of oxygen. For shock, opium and stimulants. *Local:* For burns of the first degree, powder with boracic acid. Puncture blisters, and cover the part with an antiseptic dressing. Burns of deeper degrees than the second must be made aseptic with 1 in 1,000 perchloride of mercury. Carbolic acid is absorbed readily, and must not be used. Antiseptic gauze dressings should then be used. Picric acid (20 grains to 1 ounce of water) is used as a dressing. It lessens the pain, and can be left on two or three days. The continuous bath may be used. If the burn be of any size, it should be skin-grafted, as the scars of burns contract very much, and may produce deformities. (*Aids to Surgery.*)

10. In case of acute anterior poliomyelitis talipes equino-varus is due to paralysis of the peronei, tibialis anticus, and the extensors of the toes. The treatment varies in different cases. If the deformity is easily corrected, and the paralysis is confined to the peronei and extensors, tendon transplantation may be performed, the tendon of the tibialis anticus being attached to the cuboid, and a strip of the tendo Achillis to the dorsal aspect of the tarsus. If the condition is more severe, it may be necessary to divide the plantar fascia and ankylose the various joints involved. The after-treatment includes massage, exercise and electricity.

TOXICOLOGY AND MEDICAL JURISPRUDENCE.

1. *Malpractice* is a failure on the part of a medical practitioner to use such skill, care, and judgment in the treatment of a patient as the law requires, and thereby the patient suffers damage. If due to negligence only, it is *civil malpractice*. But if done deliberately, or wrongfully, or if gross carelessness or neglect has been shown, or if some illegal operation (such as criminal abortion) be performed, it is *criminal malpractice*.

2. "When a body entirely unknown is found, the decision as to identity may be simplified by exclusion, so that such general questions as those of sex, race, age, height, and weight, are first settled; then with the help of the clothing, vocational stigmata, and the circumstances under which the body is found, much may be learned as to the individual and the class of life from which he came. The color, amount, and character of hair, color of eyes, the condition and number of the teeth, and general type of features, the presence of deformities, tattoo marks, and cicatrices, will, in the entire and fresh, unmutated body, give us a basis on which to rest a thorough and complete identification. It frequently happens, however, that bodies of unknown dead are found after the lapse of days or weeks, or, when found in water or in the woods, may be so disfigured as to make useless most of those means of identification which are most commonly used. In such instances one makes the most of those points which are at his command. When from decomposition, or for other reasons, it becomes necessary to bury or in other ways dispose of the body before identification is complete, proper photographs should be taken, and the contents of the pockets, and other possessions found on or about the body, which may assist in identification, should be retained for future reference."—(*Dwight's Medical Jurisprudence.*)

3. The presence or absence of the usual signs of pregnancy. The condition of the breasts may be of some importance. Much will depend on: (1) the time that has elapsed between the abortion and the examination of the woman, (2) the period of pregnancy when the abortion was performed, and (3) the manner in which the abortion was performed.

4. *In death by drowning:* The surface is pallid, the face appears tranquil, the eyes and mouth being partly open. The skin often has the appearance known as goose-skin, and, if the body has lain upward of twelve hours in the water, that of the hands and the feet is sodden by inhibition. The most important external sign is the presence on the mouth and nostrils of a fine froth (possibly blood stained), composed of air, mucus, and the medium in which drowning took place; if the body remains three or four days in water, the froth disappears. Exceptionally, fragments of weeds or other small objects may be found tightly grasped in the hands. On opening the thorax the lungs, gray in color, with reddish staining are seen to be very voluminous, a condition known as ballooning, partly due to infiltration of the lung tissue with some of the medium in which drowning took place, and partly to true edema. The lung substance is inelastic and pits on pressure. On section, fluid and froth resembling that found on the lips exude from the divided air passages. Minute subpleural hemorrhages

are not infrequently present, and the pleural cavities may contain fluid. The stomach often contains water or other liquid which was involuntarily swallowed during attempts at respiration. Occasionally some of this fluid is forced by vital action into the intestines. With one exception, the remaining appearances are those met with after death from asphyxia. The exception is constituted by the blood, which is not only dark colored and fluid, as is usual after death from asphyxia, but is also diluted by the imbibition of water from the stomach and lungs.—(*Quain's Dictionary of Medicine.*)

5. *Rape* has been defined as being the carnal knowledge of a woman against her will. But the element of will may or may not enter into the case; consent if it be obtained by fraud or from one mentally deficient, or under age, does not relieve the criminal from the charge of rape. Rape may also be perpetrated when the victim is unconscious or in such other condition as to interfere with the action of the will.

Medical evidence is usually based on: (1) The presence or absence of bruises, wounds, or other signs of injury upon or about the genital organs. (2) The presence or absence of seminal stains or blood-stains upon the person or clothing of those concerned, and the presence or absence of spermatozoa in the vagina. (3) The presence of venereal disease in either party.

6. *In case of poisoning*, the following rules have been suggested: (1) Lose no time; (2) use the best remedy available at the moment; (3) get rid of the unabsorbed poison; (4) stop the action of such poison as has been absorbed; (5) remedy such mischief as has been done; and (6) keep the patient alive, if possible.

7. *Two reliable emetics:* Apomorphine hydrochloride, gr. 1/10, by hypodermic; zinc sulphate, gr. xv.

8. *Symptoms of cocaine poisoning:* Fullness of head, general sense of oppression, nausea, vomiting, headache, giddiness, rapid pulse and respiration, nervous excitement, dilated pupils. *Toxic dose:* Half a grain has caused death.

9. *In poisoning by opium:* The symptoms are of slow onset, drowsiness is followed by stupor and lethargy, the muscles are relaxed, the patient cannot walk, the face is pale, and the pupils are contracted, respirations are very slow.

In acute alcoholism: There is a stage of excitement prior to the stupor which comes on rather suddenly, the face is flushed, and the pupils are generally dilated, respirations are regular.

10. *Chemical antidotes* act as such by uniting chemically with the poison and thus converting it into a harmless or insoluble compound; as magnesium sulphate in lead poisoning, which converts the lead into insoluble lead sulphate.

Physiological antidotes act as such by combating the physiological action of the poison; thus opium will counteract the dilated pupil caused by atropine.

HYGIENE.

1. *Malaria is transmitted* by the bite of the anopheles mosquito. *Prophylaxis of malaria:* Individuals should use mosquito netting around their beds and wire gauze in doors and windows so as to keep out the mosquitoes as much as possible. During residence in malarial districts quinine should be taken every morning before breakfast. All pools, stagnant water, etc., where *anopheles* may breed, should be removed. All mosquitoes, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darkness, opportunities for infection may be avoided. Occasional fumigation with formaldehyde or sulphur is also beneficial.

2. Flies (which may carry typhoid, cholera, dysentery, tuberculosis, and possibly scarlet fever, smallpox, measles, pellagra and anterior poliomyelitis); and rats (the flea on the rat carries bubonic plague).

3. The best way to dispose of sputum is to burn it; the best disinfectant is probably 5 per cent. carbolic solution or 2½ per cent. cresol.

4. A diphtheria patient remains infective so long as any membrane or discharge remains, and while any bacilli can be found on bacteriological examination; generally about four weeks. The infective period may be believed to have been passed when the patient is free from all signs of congestion or rhinitis, and when continued bacteriological examination is persistently negative.

5. *Trichina spiralis* is a nematode worm which, in its adult stage infests the intestinal tract of man and other animals (chiefly mammals); the larvæ are found in the muscles. The worm is most commonly found in man, hog, rat, guinea-pig and rabbit.

PERIOSTITIS AND OSTEITIS

AS A CAUSE OF LOCAL PAINS AND SO-CALLED NEURITIS
AND NEURALGIA.

BY CHARLES L. DANA, M.D.

NEW YORK.

PROFESSOR OF NEURALGIC DISEASES, COLUMBIA UNIVERSITY MEDICAL
COLLEGE.

ABOUT seventy-five years ago, Valleix wrote a treatise on neuralgia and described its painful points. He used a classical grouping of neuralgias which has continued in literature ever since. I have myself paid obeisance to the Valleix points and the well ordered arrangements of the academic neuralgias. But as experience has increased and neuropathology become a more accurate science I have come to doubt and finally quite disbelieve in the merit of these old neuralgic formulæ.

If by neuralgia is meant a chronic or subacute malady, functional in nature and characterized by pain along a nerve, one must limit its existence to a few types and call it a rare disease.

Its place has been taken in a degree by the term neuritis, which has of late become a common, one might almost say, a "smart" disease. But unfortunately neuritis is a term now used with as little real definiteness of knowledge as neuralgia. It is often only the refuge of a confused diagnostician. One may see patients with almost every painful neurosis from tabes to myelitis who say that they have been told they had neuritis. Inflammation of nerves, to be sure, is not so very rare, but one can not have neuritis without some of the cardinal symptoms: muscular weakness, wasting, reaction of degeneration, objective sensory disturbance, and tenderness along the nerve.

Reflex pain is frequent and is a legitimate diagnostic term but it has not the darting paroxysmal character of neuralgia or the objective symptoms of neuritis.

In recent years some neuralgias, notably sciatica, have been shown to be of arthritic origin and character, and the routine treatment of sciatica now is to bind and immobilize the limb and pelvis. A genuine sciatic neuritis is a rather rare disease.

As we pass along the list of classical neuralgias we can easily more than decimate it. Thus trigeminal neuralgia holds its own as a clinical entity but it has an organic basis usually, and is probably an anginal neurosis. Cervical neuralgia, so-called is usually only a migraine, or a myositis, or something allied thereto. Brachial neuralgia is usually a low grade of neuritis. Intercostal neuralgia is almost never seen and when it exists is due to tabes

or an acute posterior ganglionitis, being then an abortive herpes zoster.

We find that most of the lumbar and pelvic neuralgias are due to pressure, reflex causes, arthritis and bone disease. In fact most of the chronic and apparently functional pains are now to be attributed to the disorders of joints, muscles, and tendons. And we have mostly nowadays to deal not with varieties of typical neuralgia but with *local pains* of occipital, brachial, intercostal, lumbar, crural, or sciatic distribution.

It has been found that some of these are due to infections attacking joints, muscles, and tendons.

I wish to offer to-night evidence that in certain cases these persistent pains are due to osteoperiostitis of acute infectious origin. I have no anatomical proof of my thesis; and this is only a clinical paper; but when one finds cases in which the x-ray demonstrates periostitis; when the clinician finds a source of infection and the toxin of this infecting organism reacts in the blood; when one makes autogenous vaccines and administers them with relief, it makes a fairly definite and logical proof that ordinary infection from the tonsils and the teeth and other sources may sometimes lodge upon the bones and cause local forms of periostitis and osteitis, causing often excruciating pain. All this is admitted in so far as the joints are concerned and we know perfectly well that certain dental, tonsillar, and prostatic infections will cause chronic inflammatory processes about the joints.

What I hope to show is that similar infections cause not so very infrequently local areas of periostitis, non-articular in site, and give rise to pains which are called sciatica or intercostal, or brachial neuralgia and other forms of painful neuroses.

It is well known that the chief causes of periostitis are tuberculosis and syphilis; also that it follows acute infections like typhoid fever and may be due to rickets and to direct trauma with infection.

I am assured by surgeons and by workers in x-ray that evidences of periostitis and osteitis are found quite frequently in their x-ray work, and that they often cannot explain them. So I infer that unexplained forms of osteoperiostitis are not so very rare. Finally, there are a great many obscure and persistent pains which are met with by the practitioners and which often reach eventually the neurologists or the orthopedic surgeons. These pains are usually first attributed to rheumatism, then to neuritis or some form of myositis or arthritis, or they are called neuralgia or reflex pains. Some of these, I think, may be explained on a periosteal theory; for periosteal and bony irritations are extremely painful affairs.

I do not like to read a paper made up of reports of cases, but I see no other way of proving my point, and I will be as brief as possible.

*Read before the New York Academy of Medicine, March 16, 1916.

CASE I.—Mrs. B., age 42, married, no children. The family history is negative. The early history presents nothing of importance. There was no tonsillar, rheumatic, or luetic history and no tuberculosis.

The patient's trouble began about four years ago and it had lasted for about two years when I first saw her.

FIG. 1.—Case I. Mr. B.

The symptoms came on without any special cause, although they were attributed to weak arches. They consisted of pains in the foot and calf of the left leg extending up gradually to the hip. These pains were increased by walking and standing and they became more extensive, so that they finally involved the whole of the leg, at times. For a while she had some pain in the right leg. These pains caused her a great deal of suffering and incapacitated her from an active life. She was obliged to lie down and be in bed a large part of the time.

During the course of the two years previous to my seeing her, she had some short intervals of partial relief, but nothing more. During this time she consulted many surgeons, neurologists, and general practitioners, and she spent some time in a sanatorium. She had arches made for her feet, and her legs were strapped and she

FIG. 2.—Case I Showing periostitis

had plaster casts made for her pelvis and thighs. She had many forms of medication, including injections of novocaine into the region of the sciatic nerve and injections of mercury and cacodylate of soda, injections of stock vaccines and of quinine and urea. She received

also large doses of iodides and was treated with heat and massage.

The diagnosis first made was that of weak arches and later that of sciatica, neuritis, arthritis of the sacroiliac and other pelvic joints.

The patient's condition varied, but on the whole remained about the same. She was growing worse, however, when she consulted me in May, 1914.

Patient was a fairly well nourished woman, weighing about 130 lbs. She was able to stand and walk, but walked with her body bent forward and unsteadily as though her leg was weak and the walking hurt her. She said that walking would cause at first pain in the calf of the left leg and this would increase and extend up and involve the thigh as far as the crest of the ilium and become so severe she had to lie down. The central areas of pain were in the lower part of the left leg above the tendo Achillis and in the upper part of the back of the thigh. Sitting down caused pain in the left buttock. (Fig. 1.)

Examination showed that the left leg was slightly smaller than the right but the difference was not abnormal. There was some incapacity to flex the foot on the leg, owing apparently to a drawing-up of the tendo Achillis. There was exaggeration of the ankle and knee jerks, left being more lively than the right. There was a slight pseudo-clonus in the left foot but no Babinski. She could not straighten out the leg or lie perfectly flat on the floor or stand up perfectly straight without its causing some pain in the leg and hip. This pain finally reached the left sacroiliac joint which was slightly tender. There was no tenderness over the nerve, no anesthesia, cutaneous or deep, no paralysis or weakness of the segments of the limb.

The hip joint was perfectly free and mobile and movements of it caused no pain. She could raise the two legs from the bed when the knees were straight but only with difficulty, and it caused pain to extend the legs fully on the thigh. Above the waist there was no abnormal disturbance found; the trunk muscles were normal, the arms and their joints were normal, and the cranial nerves were normal.

Dr. Thomas W. Hastings was called in and he made examinations of her blood, of pus found in the roots of the teeth, and of the urine. The blood was found to be negative to lues, the gonococcus, and 12 strains of streptococcus, but positive to *Streptococcus viridans*. The pus from the teeth showed the presence of *Streptococcus viridans*. There was no anemia or leucocytosis.

Examinations of the other organs and of the urine were negative. Cultures were made of the streptococcus and the vaccines were prepared and she was treated with these vaccines at varying intervals during the following year and a half.

The patient almost immediately began to improve. She had some relapses, but never got back to the point where she was when I first saw her.

In July, 1915, it was decided to remove all the teeth in which the abscesses existed. Improvement followed this partial removal of the teeth in July. In November, 1915, all the teeth were removed. Since then the patient has been practically well.

The x-ray made in the spring of 1914, when I first saw her was reported to be negative, but that made in November, 1915, by Dr. L. G. Cole showed irregularity of the surface and periostitis of the pubes and ischium. (Fig. 2.) The hip joint and sacroiliac synchondrosis were normal. There was evidence of a slight osteoperiostitis of the lower end of the tibia and fibula with enlargement of the sheath of the tendo Achillis.

The conclusion from this history is that the patient had an infection which produced a low grade of osteoperiostitis involving the lower bones of the left leg and later the bones of the pelvis, but not involving any of the joints. The general infection caused also some Achillis tenosynovitis. The osseous invasion must have been slight and yet it caused very persistent pains and incapacitated the woman from standing or walking very much for two years.

The fact that no other lesion was demonstrable and that the patient responded to the use of vaccines and the removal of all foci of infection make the conclusions that this long case of painful invalidism had the origin and pathology which I have described.

The history of the case is supplemented by laboratory examinations of the blood and of the urine

and bacteriological examinations and reports of the *x*-ray men.

The *x*-ray examination made in May, 1914, by Dr. Caldwell showed only positive evidence of abscesses at the roots of two of the teeth.

FIG. 3.—Case II. Mrs. K.

A nitrogen partition made by Dr. Hastings in May, 1914, was practically negative. There was a slight trace of indican.

The nitrogen partition made by Dr. Hastings in June, 1914, again was negative except for an increase in indican.

Examination of the stools by Dr. Hastings in May, 1914, showed nothing abnormal.

The examination of the blood for hemoglobin and cell-count made in 1914 and in 1915 showed that the blood was normal with no increase in leucocytes.

Examination of the blood for Wassermann by Dr. Kaplan in May, 1914, was negative.

CASE II.—Mrs. L. K., married, aged 25. The family history is not very complete. The mother died at forty, the cause being unknown. The father is alive and well.

FIG. 4.—Case II. Showing areas of osteosclerosis at point marked X and neighborhood. (Dr. William Klein.)

The patient has always been well up to the time of the present illness. She married in 1911 and gave birth to a healthy child in March, 1912.

In July, 1912, she complained of pain in the right thigh, and a tentative diagnosis of sciatica was made.

She came to see me in June, 1913, in consultation with Dr. William Klein. Her statement was, however, that in July, 1912, she woke up in the night with pains in the right groin. These, later, extended into the back and buttocks and ran down to the knee. They seemed to run largely in the course of the lower lumbar and sometimes in the anterior crural nerves and extended down below the knee on the right side. The pains were increased by standing and walking. She had been treated for sciatica for a number of months, and had received subdural injections of saline solution without benefit. She was then taking 45 grs. of aspirin a day, which temporarily gave her relief. She was also relieved by rest.

Examination showed no objective disturbances of the parts affected. The knee-jerks and ankle-jerks were normal. There was no disturbance of gait or station; no atrophy or paralysis of the legs; no tenderness, particularly in the course of the nerves; no anesthesia; no disturbance of the sphincters. The patient complained of severe and more or less continuous pain in the right thigh about in the region indicated by Fig. 3.

There was no tumor or evidence of growth either by external or rectal palpation.

The various bodily organs and the blood were normal. The Wassermann test negative.

I concluded that the case was one not of nervous but of bony disturbance and advised an *x*-ray. This showed certain peculiar spots on the ischium. The *x*-ray photographs were made by three men, all with the same results.

The patient was finally taken to Mr. Sinai Hospital, where she was operated upon by Dr. A. A. Berg.

Dr. Berg writes me that when he operated, the patient presented a tumor-mass corresponding on the right ischium near the symphysis pubis. He cut down upon this region and removed a considerable part of the apparently diseased part, which had been thought to be sarcoma; but Dr. Berg states that the bony tissue at the time of operation did not appear to be of sarcomatous or of tuberculous nature.

The pathological examination was made by Dr. Mandelbaum who writes me that the bone removed showed simply eburnation with no suspicion of any tumor or tuberculosis.

The relief from operation was immediate and the patient has been well ever since, and it is now a period of two years.

The accompanying slide shows the appearance of the pelvic bones in the *x*-ray photograph. (Fig. 4.)

No one seems able to interpret exactly the nature of this bony trouble, but it is certain that there was some inflammatory or sclerotic process of the pelvis, which produced pains radiating down the groin and along the back and outer side of the hip in the region superficially of the ilio-inguinal and genito-crural nerves.

The part most affected was the ramus of the ischium. The muscles attached to this part are the external obturator, the gracilis, and the adductor muscles of the thigh, which, however, were not involved in any apparent irritation or spasm. The muscles here are supplied by the 2nd, 3rd and 4th lumbar and the sensory nerves which were involved in pain correspond about with the distribution of the 1st, 2nd and 3rd lumbar segments on the back and side of the thigh, so that it is easily understandable that a local irritation at the points of lesion would cause pains in the region where the patient did, in fact, suffer. For the pains, in fact, were in the distribution cutaneously of the 5 lumbar segments.

I mention these facts since some suggestion has been made that the pains were psychical, because of their rapid disappearance after operation, and because of the benign character of the condition found on operation. The locality of the pains, however, and the absence of other symptoms show that the pains were due to the lesion that was attacked so effectively by the operation.

No dental or blood examinations for infection were made in this case.

CASE III.—Mr. T. A. P., aged 55, married. The father is living and healthy. Mother died of Bright's disease. There has been no rheumatism in the family.

FIG. 5.—CASE III. MR. P.

Patient had gastric ulcer when a young man. He has been active, hard-working, very temperate and regular in his habits, with no record of tuberculosis or lues. He has never had any attack of acute or chronic rheumatism, or of tonsillitis. He has had pyorrhea for a number of years, and he has suffered at times from attacks of dyspepsia.

About six months before I saw him, in the summer of 1915, he began to have pains in the right thigh. These caused some difficulty in walking. The pain has been gradually increasing and finally has become practically chronic, but lessened by rest and increased on walking, sitting down, or on rotating the thigh.

When I saw him in October, 1915, he appeared as a strong, well-nourished man, walking with a good deal of stiffness on account of pain in the right thigh.

The general examination showed nothing of importance. Heart and lungs and kidneys were normal.

FIG. 6.—CASE III. Showing periostitis.

The station, reflexes, and objective sensation were normal. The cranial nerves were normal.

The pain from which he suffered was located in the front and side of the right thigh and knee and he had to keep changing his position to get relief. Walking

would make it more severe; and in sitting he had to shifting his position often to get relief. It was relieved in the main by lying down. (Fig. 5.)

Examination showed that he was unable to extend the trunk fully on the thigh or rise from a low step, or step up a high step with the right leg without pain. He had some difficulty in freely abducting and adducting the leg and he could not flex the thigh fully on the abdomen. Nevertheless, the hip did not seem to be definitely involved. The thigh could be manipulated quite freely, and there was no tenderness on jarring him or on pushing the thigh against the pelvis. He had no atrophy of the thigh. The knee-jerks were present and lively, the left a little more so than the right. The limbs showed no anesthesia, superficial or deep.

The case seemed to be one of pain due to bony disease and he was sent to Dr. Lewis G. Cole, who made the following report:

"The frontal and maxillary sinuses and ethmoid cells show no evidence of involvement. The roentgenograms and films of both sides of the jaws show distinctly the contour and structure of the alveolar process, and the teeth, their roots and fillings. There is no evidence of an abscess around any of the teeth. There is, however, a pericementitis and some recession of the alveolar process around the shaft of the teeth. This is especially marked in the center of the lower jaw, where there is a destruction of the bone between the teeth, but not around the apices. Roentgen Diagnosis:

"Stereoscopic roentgenograms of the hips show distinctly the contour and structure of the bones and the muscles and soft parts. I am unable to detect any change in the head or neck of the femur. However, there is a periostitis of the inner surface of the pelvis, and particularly of the inner surface of the horizontal ramus of the pubes, on the right side. This is evidenced by the raising and the thickening of the periosteum. This is the second case of this sort that we have had inside a week [referring to Case I].

"Roentgenograms of the lumbar spine show distinctly the bodies of the third, fourth and fifth vertebrae and the sacrum. The bodies of the vertebrae are normal in size, shape and position, and the spacing between them is adequate. I am unable to detect any lesion in this region to account for the symptoms." (Fig. 6.)

The patient was also sent to Dr. T. W. Hastings who made a Wassermann test of the blood which was negative, and fixation for the gonococcus and 12 strains of streptococcus, which was also negative. Examination of pus from the gums showed the presence of *Micrococcus albus* and *Streptococcus viridans*. Examination of the feces by Dr. Hastings showed nothing but an excessive protein putrefaction and excess of urobilin. A nitrogen partition was also made of the urine without any very definite results.

Here again is a case of periostitis and ostitis involving the bones of the pelvis but not the hip joint and causing very severe and agonizing pains. Here, too, the cause of the infection was not discovered; but it is plainly not due to the ordinary causes of periostitis. The pains were so severe and so difficult to relieve that it was feared there was a malignant growth. Eventually these proved to be the case and the periostitis must have been due to cancerous irritation.

CASE IV.—Mr. J. B.; aged 25; single; teacher by occupation. The family history showed evidence of arteriosclerosis, but not of any form of rheumatism.

As a boy was rather delicate, and in the first two or three years of his life he had rickets. He had diphtheria at the age of six, and received antitoxin. Later he had some enlarged glands in the neck which disappeared. He had appendicitis and was operated on at the age of twelve. As he grew up he developed into a fairly strong man and indulged actively in athletics.

He had never had an attack of rheumatism, but he had had two attacks of tonsillitis and his tonsils were removed. He has very good teeth and has never had any luetic or gonorrheal infection. He was temperate in his habits except that he was inclined to overdo his work, both mentally and physically.

While a junior in college after playing squash, he noticed in the course of the evening that his left leg was painful and weak, though he had not been hurt during the game. He kept it tightly bound up in

flannels and in a few weeks he got well. The pain returned some months later, and it has been with him at times ever since, but in the last year it has become worse and distressed him very much. It was at first not very well defined, but finally centered over the left thigh. About a year before my examination he had de-

FIG. 7. Case IV. Mr. B.

veloped a certain amount of depression and neurasthenia and lost weight.

I saw him first in February, 1913, about four years after the pain was first noticed. At that time he was feeling well, except that he suffered from the pain in his left thigh; and it was for this that he especially consulted me. He was a well-developed, active young man, sound in all his organs, with no bad habits and no lues. The pain was rather diffuse and was located about the anterior and external part of the thigh. (Fig. 7.) The pains in his legs were relieved by rest and brought on by active exertion. There was no tenderness of the muscles; no atrophy; no weakness; no anesthesia or hyperesthesia of the parts. The gait and station were normal and the reflexes were normal.

Examination of the blood and heart and kidneys showed them to be normal.

The patient had been treated for neuritis, for myositis, and for neuralgia without any result. I could find no evidence of any objective disorder of the nerves or muscles, and I had an x-ray taken by Dr. Caldwell. This showed a thickening of the upper part of the left

FIG. 8. Case IV. Showing periostitis of upper part of the left femur at point marked X.

femur with a condition which was regarded as an osteitis, more than a periosteitis. (Fig. 8.) I could not discover any cause of the trouble. There was no tuberculosis and no syphilis, and no evidence of trauma or local infection.

Tests made of the blood made by Dr. Hastings failed to reveal any complement-deviations; and the teeth were sound.

The patient was put upon tonic measures and given moderate outdoor work and massage. He gradually improved, and for the past year he has had very little trouble with the leg. He is still, however somewhat conscious of it and the pain will come in this part after any severe exertion.

The second x-ray made three years after the first examination shows the condition of the bone to be practically the same.

In this case, I am obliged by process of exclusion to attribute the pain to osteoperiostitis. I am unable, however, to say what is the cause of the trouble. We can certainly exclude ordinary causes such as tuberculosis and syphilis and trauma with infection. I am unable to exclude, however, an infection by some microbe like the *viridans*.

It is possible to suppose that during violent muscular effort the periosteum was torn up or ruptured and an osteitis supervened. This is a somewhat far-fetched theory, however, because the muscular attachments in the joint where the osteitis is present are very few. The vastus externus and the gluteus maximus and minimus are attached near this region, also the upper part of the crureus. The direct action of these muscles, however, produces no pain and it was only by a general and more violent and continued exertion that pains were brought out.

The conclusions which I draw from these experiences are:

1. That acute infections from the teeth, tonsils, and other foci may cause local forms of osteitis and periosteitis.
2. That this fact must be reckoned with in diagnosing neuralgia and other persistent and distressing local pains.
3. That the joints are not the only regions attacked by acute infection; and that the arthritis explanation of pains in the back and extremities has been perhaps overdone. So-called "sciatica" for example, is not always arthritic or myositic or neuritic.
4. That further study is needed to corroborate these findings of mine, and to determine the source and nature of the infections that produce them.
5. That syphilis and tuberculosis do not play so large a part as supposed in the causation of these minor types of osteoperiosteitis.
6. That "neuralgia" as usually defined is a very rare disorder, and its diagnosis is to be made only after careful examination of muscles, bones, nerves, nerve centers, and sources of reflex irritations.

I am indebted to Dr. Wm. Klein for notes of one case and to Dr. Hastings for much helpful cooperation in this work.

53 EAST FIFTY-THIRD STREET

Treatment of Rabies with Quinine and Phenol.—Frank S. Fielder, after reading the report of a case of rabies treated successfully with quinine and urea hydrochloride, receiving 90 grains intravenously, decided to try the treatment on a child who had been treated irregularly by the Pasteur method and who developed the typical symptoms of the disease. The drug had no apparent effect and the necropsy showed the Negri bodies in the brain. Four additional cases treated by either intravenous or subcutaneous injections of quinine and phenol were likewise unaffected by the treatment. The writer concludes that the case reported as cured was probably not one of rabies and that these drugs have no specific effect on rabies.—*Journal of the American Medical Association*.

AUTOSENSITIZED VACCINES.*

BY M. G. WOHL, M.D.,

OMAHA, NEB.

MUCH has been done in the field of vaccine therapy, yet this method of immunization before and during disease is not being fully appreciated by the practitioner. It is true that a great deal in vaccine therapy is not based upon established scientific data, yet the results obtained by vaccines have been so brilliant in cases bacteriologically diagnosed and carefully guided, that it becomes imperative to approach the question unbiased to recognize its limitations and to understand the theory upon which the employment of vaccines depends.

The prophylactic use of vaccines has been known since the time of Jenner and Pasteur. Recently its usefulness has been demonstrated in immunization against typhoid fever.

The application of vaccines for treatment of already existing disease has been given wide popularity by the work of Wright and his pupils. It is this phase of vaccine therapy that we propose to consider in the present writing.

When an infectious disease attacks the organism a contest ensues between the offensive properties of the germ and the defensive mechanism of the body; the factors upon which the combat depends have been variously explained. Yet, the theory put forth by Vaughan is the simplest and most rational.¹

The infecting agents as we know them, bacteria, moulds, yeasts, and protozoa, are living proteins, which are capable of growth and multiplication. Like all living units, in order to exist they must get food of proper kind to fit into their structure. Germs that cannot utilize the protein of an animal are not pathogenic for it. So that the mere presence of a microorganism is not enough to produce disease.

Organic units live by means of ferments. There are ferments of two kinds, analytic and synthetic. The analytic ferments split up the food into proper building stones, "Bausteine," while the synthetic arrange them in the cell molecule. These ferments are usually spoken of as extracellular and intracellular.

The extracellular diffuse through the medium, while the intracellular remain within the cell and do the constructive work. The ferments are specific in the sense that they can split up a certain protein; besides this there are a number of other factors which regulate the relationship between ferments and substrate, such as temperature, environment, etc.

This explains why some animals are susceptible to certain diseases, while others remain immune. For example, ordinary sheep are easily infected with anthrax, while Algerian sheep are immune to it. Or, as Koch has shown, the bacilli of mouse septicemia and cocci that induce necrosis multiply simultaneously in the white mouse, while the field mouse, when inoculated with mixed cultures, responds to the latter and the former fails to develop.

The introduced foreign protein provokes the formation of ferments which act now on the defensive and break up the foreign substances, *e. g.* bacteria, into several groups, a primary group (archon, key-stone) with which are connected secondary and tertiary groups.

*From the Pathological Laboratory of the Nicholas Senn Hospital.

It is also Vaughan's idea that the primary group is set free by the ferments and is responsible for the symptoms of disease, for it constitutes the poisonous group of atoms of the molecule. The secondary and tertiary groups are non-poisonous; they stimulate the body cells to the formation of ferments or enzymes, which have the power of rapidly digesting a homologous protein. Thus, according to Vaughan, the pathogenicity of a virus is determined by its ability or inability to grow in the body of an animal. Its inability to do this may be due to the fact that it either cannot utilize the body protein for its food or because the ferments of the body cells digest the invading bacterial protein. To cause the formation of such ferments is being aimed at by the administration of vaccines. Vaccination is brought about by the introduction of dead bacteria, either sensitized or not, or attenuated live bacteria.

Immunization by live bacteria is more substantial, yet there is danger of the vaccine proving too virulent and causing the actual disease; or the individual may become a carrier.

Vaccination with killed bacteria is the method adopted at present in human medicine. Immunity

FIG. 1.—M. R., before treatment: had been subject to furunculosis for a number of years.

established by killed germs is durable, lasting from three to six months or even longer. However, during the process of immunization, local or general symptoms may arise. In our experience with autogenous vaccines we have found that if the patient develops a marked local reaction (redness, induration at the site of the injection), and moderate constitutional symptoms, such as slight rise in temperature, slight discomfort, etc., the ultimate results derived from the vaccines are more satisfactory than if the vaccines are not followed by any temporary local or constitutional changes. We have learned to welcome "reactions" during immunization rather than to fear them.

The *modus operandi* of bacterins, then, is to stimulate the body cells to the formation of protective ferments, which consist of amboceptor and complement. The amboceptor of the ferment sensitizes the bacteria and when the complement acts upon them they are digested.

When dead bacteria are used as vaccines they should retain as much as possible the potencies that they exhibit in the human body, for bacteria

may undergo different transformations upon different culture media. For example, the pneumococcus hardly ever exhibits upon artificial culture media the capsule formation, or, as Rosenow² has shown that hemolytic streptococci may become con-

Fig. 2.—M. R., after treatment with autoserobacterin.

verted into streptococci mucosi, pseudopneumococci, etc.; therefore, vaccines should be made up from bacteria which are changed as little as possible.

We prefer to use primary cultures whenever possible for the preparation of our vaccines, and we subject them to as little artificial change as we can possibly help. A point which is of great importance and most frequently overlooked is the too rigid sterilization of bacterins. It should be borne in mind that too high a temperature destroys the antigenic properties of vaccines. It is our rule, therefore, to sterilize vaccines from thirty to forty-five minutes at a temperature which ranges from 56° to 58° C.

If vaccines are used at all the autogenous should be preferred. Of course, the use of vaccines makes a prerequisite of a bacteriological diagnosis. This is really the only scientific method of approaching

the treatment of infection. The practitioner who uses a mixed vaccine often accomplishes little; on the other hand, he adds the danger of introducing into the body foreign proteins.

Vaccines are of value in chronic and subacute localized conditions, where complete healing is prevented, which is probably the result of lack of protective ferments (antibodies) in the blood; for little of the antigen is absorbed. The stimulation of healthy tissue by the specific germ (autogenous vaccine) is followed in such cases by the formation of bacteriotropic substances. When these are brought to the lesion the result is accomplished. It is our custom during immunization with vaccines to apply hot wet dressings to the part affected for the above reason.

The employment of vaccines in bacteriemias, although contrary to scientific principles, yet has been found very useful by different observers. The class of cases in which we found vaccines of great service will be enumerated later as we are using a somewhat modified method for their preparation.

Sensitized vaccines have proved very efficacious. They were introduced into medicine by Besredka in 1902.³ By sensitized or serobacterins we understand a suspension of bacteria which is mixed with immune serum and allowed to macerate a few hours, after which the serum is removed, the bacteria washed in a physiological salt solution, and again suspended in saline, standardized, and dilutions made accordingly.

During the process of sensitization the bacteria become saturated with their specific antibodies, as Ehrlich and Morgenroth have shown that bacteria mixed with their corresponding antibodies unite to the exclusion of all other substances present in the serum. When the serobacterins are injected into the body they are immediately acted upon by the complement and bacteriolysis results. The liberation of the non-poisonous group of the bacterial protein occurs, and it stimulates the body cells to the formation of defensive ferments. Sensitized vaccines are generally recognized to be superior to the unsensitized. They have been used in typhoid fever, rabies, cholera, and other infectious diseases.

Besredka himself reports the application of sensitized vaccines in ten thousand cases, without any

Fig. 3.—Case of puerperal sepsis. Chart showing improvement following upon the administration of autoserobacterin. Streptococcus group was found in the blood.

serious results following their administration. The advantage of sensitized vaccines is a more rapidly acquired immunity. The immunity acquired is durable and lasting.

The method employed for sensitization of bacterins, we believe, is not without its faults. As it is generally admitted, the failure of many bacterial sera in therapeutics is because they are produced in the lower animal and do not find suitable conditions for their action in another species, such as man.⁴ The antibodies of such a serum are beyond question somewhat different from those in the patient. Therefore, it seems rational to assume that the action of a sensitized vaccine would be enhanced if we used the patient's own serum for sensitization, as under these conditions the patient's own antibodies would be brought into contact with the specific virus.

Working on this basis we are at present using, at the Nicholas Senn Hospital, autogenous vaccines sensitized with the patient's own serum. Although our cases treated by this method are too few to warrant any definite conclusions, yet the results have been so gratifying that we cannot help believing that they are superior to ordinary sensitized vaccines.

Another rather technical point, which is, however, of great importance, is the freeing of bacteria from the immune serum. By washing the bacteria with physiological salt solution, we are apt, I believe, to disunite the antibody from the active substance and thus fail to accomplish the desired result. Besides, as we have pointed out elsewhere,⁵ it has been shown that complete absorption of antigen by antibody is impossible; therefore, by washing the bacteria we discard some antibodies which are of importance in raising the resistance. On this account we do not separate the serum from the bacteria, but are injecting into the patient the entire mixture of vaccine and serum.

Although several men have used a mixture of serum and vaccine, in certain diseases, *e. g.* in hog erysipelas (Lorenz⁶), in plague (Calmette and Salimbeni),⁷ yet, according to Friedberger,⁸ working with rabbits, the immune serum after sensitization shows an inhibitory action. This was not the case with our patients. On the contrary, the action of the autosensitized vaccines proved superior to the sensitized.

The technique for the preparation of autosensitized vaccines has been given elsewhere.⁹ (A somewhat similar method, though independent of ours, is being employed at the Murphy clinics.) The cases treated by the above described vaccines at the Nicholas Senn Hospital included the following: Otitis media chronica, 3 cases; Cystitis, 2; Furunculosis, 6; Erysipelas of the face, 1; Acne, 1; Gonorrheal vaginitis, 2; Infected compound fracture, 1; Puerperal sepsis, 1 (in this case commercial antistreptococcic serum was used for sensitization, on account of inability to obtain sufficient blood from the patient, because of her severe anemia); Rabies, 1 (ten usual doses of Pasteur anti-rabic vaccine was given and then blood obtained for sensitization).

In cases where the agglutinin content of the patient's serum is low, immunization with simple autogenous vaccine is followed for two or three doses and then serum is withdrawn for sensitization of subsequent doses. The accompanying illustrations show the effect of the autosensitized vaccines.

TRANSPORTATION OF THE WOUNDED ON THE AUSTRO-RUSSIAN FRONT.*

BY E. KILBOURNE TULLIDGE, M.D.,

MIDDLETOWN, CONN.

FORMERLY CAPTAIN-SURGEON, AUSTRIAN ARMY
MILITARY SURGEON FRENCH RED CROSS.

GREAT improvement in the transportation of the wounded from the front has been made since the war first began, and now, instead of the crude trucks and empty freight cars used during the first days of the war, thoroughly equipped ambulance trains are in operation. Each of these trains is provided with a staff of not less than two surgeons and one physician, the latter to care for those cases of infectious and contagious diseases met with, and from three to four female nurses.

The most complete of these trains comprises from ten to forty coaches. Two for the surgeons', physicians', and commandants' eating and sleeping quarters, two for attendants' cooking and eating quarters, one for an operating room, one for a magazine and medical store room, and the remaining equipped for the transportation of the wounded.

The operating room is of the latest and best type, containing all the necessary requirements for the most intricate operations which are performed after bringing the train to a stop upon a siding. Here food is prepared and reading matter distributed to those able to read and every comfort of the soldier is attended to. The trains of the Maltese Ritter Orden, Von Ostreicher und Boheme are equipped with an automobile ambulance, which is used to transport those wounded at a distance from the railroad upon which the train has taken up its station.

Two operating tables enable two operations to be performed at the same time. This is often necessary when from 500 to 1,500 wounded men are brought in during the course of a day.

The beds are attached to upright iron columns wedged together to a degree of absolute immobility and attached to the floor of the car, thus allowing the patient to rest with ease and comfort until the base hospital is reached. The spring mattresses are furnished with clean linen and blankets each trip, and every possible sanitary convenience has been thought out and installed. The beds are detachable and can be used as stretchers, being carried, if necessary, right onto the field.

The base hospitals are filled with young and old, all eager to help. Some of the women work very hard and go with the trains, making at times good nurses. Others, however, unfortunately play the lady and are hard to manage.

These surgical trains, as they are called, are of great service, as are also the ambulance motor cars, but unfortunately it is impossible to use them every-

where, especially in the Boukovina and Carpathians, because of the mountainous character of the country and the terrific snowfalls which, in many regions, completely prohibit traffic of any kind. Horses are the only available means of conveyance, and the

FIG. 1.—Wounded soldiers awaiting transportation from the field after the battle of Stanislaw.

most suitable abode or shelter is commandeered for surgical and medical purposes. Often this is but a farm house, stable, or railroad station in ruins. If time permits, these are first whitewashed and cleaned.

A bench, ordinary household table, or wooden stand answers the purpose of an operating table. On one occasion I was forced to use the head-board of an old wooden bed from which we knocked the legs and covered the body with a rubber sheet. Shelter for the wounded was many times inadequate and they were forced both before and after the operation to lie in the open, snow-covered fields upon crude stretchers or blanketed boards.

One instance of this I shall long remember. It occurred at Delatyn in the Carpathian Mountains. We arrived in a blinding snowstorm of already three days' duration to find over two thousand wounded Austrians, Hungarians, Russians, Poles, etc., lying in the open field with no shelter save a blanket between them and nature's snow-clouded sky. Many of these poor chaps were found, upon inspection, frozen to death as they lay. Others died from the lack of attention and many of those who were fortunate enough to receive care were too weak from exposure to withstand the treatment.

The first-aid treatment of wounds of the head or cranium is confined principally to stopping the hemorrhage, treating the shock, and binding the head, after it has been cleansed, as well as the circumstances will permit, in a skull-tight bandage secure enough to remain in position during transportation until a suitable operating hospital is reached, where after-care can be administered. Wounds of the head occur in the ratio to other wounds of the body as one to twenty and are most commonly met with in the trench form of fighting, although shrapnel plays a big factor in the etiology. This is especially true upon the Russian front.

Unfortunately facilities for speedy, rapid, and proper transportation are not common, long periods elapsing at times between the infliction of the injury and the time when it is operated upon and the symptoms relieved. In this interval, sometimes as long as five to ten days, infection develops rapidly with severe sepsis, attending convulsions, internal hemorrhage, coma, etc.

In one of the largest clinics in Vienna the mortality for skull and brain involved wounds ran as high as 89 per cent.; in another 78 per cent.; in

Budapest, however, it dropped to 65 per cent.; while still nearer the front, in Miskolcz, Kolomea, and Krakow, it went still lower, to 52 per cent.

The results of trephining for penetrating wounds of the skull, with much laceration of the cerebral substance, especially with foreign body involvement, do not confirm the high hopes that were originally felt in earlier campaigns. At the battle front, even in the most serious cases, operations immediately performed (in the first twenty-four hours) with the removal of bone splinters and antiseptic cleansing of the wound may and often do give results which exceed all hopes. Prostration, stupor, coma, and even partial paralysis may disappear, fever and vomiting cease or diminish, the mind clears up, and there is every indication of a return to a normal condition. However, although considerable improvement is obtained by trephining immediately in both serious and light cases, the success lasts but a short time, slow or rapid encephalitis arises and carries off the patient as do other unexpected complications.

With the work upon the field the field hospitals are of necessity constantly changed or transferred great distances and the wounded forced back to safer quarters quickly, without regard for person, nature, or condition of wound, time, or distance. Some go in autos, some in carts, some on foot, and others in freight cars, lying upon straw-covered floors that jar and jolt the remaining endurance into an unconsciousness from which there is many times no awakening.

The transportation of the wounded and their immediate care is of the most importance and the greatest care of the medical military authorities. Operations under primitive conditions, as those performed by the regimental surgeon, who is forced to

FIG. 2.—Interior of a field hospital.

work in hastily transformed stables, churches, railroad stations, sheds, and caves, cannot be censured, criticised, or expected to produce results other than those following temporary relief.

Not only wounds of the head, but those of the

abdomen suffer because of these crude, ill-provised operative surroundings and transportation.

Bouvier states that "thirty-two laparotomies performed by Caudrelier and himself comprised seventeen cases of perforation or laceration of the small intestine and five cases of perforation of the large intestines, etc. Altogether, these thirty-two laparotomies resulted in fourteen recoveries and eighteen deaths, that is, forty-five per cent. of recoveries." This is a very good percentage. It may be said that Bouvier and Caudrelier were much favored by the exceptional situation of their ambulance in proximity to the trenches. This is true, but, on the other hand, they also had the disadvantage of the situation. They operated systematically in all cases no matter how serious they were. Certain patients who had lesions such as a severed external iliac artery or renal artery, a rupture of the liver, eight cases of severed small intestine with three cases of severed transverse colon, etc., would certainly have not been operated on if they had had to undergo transportation for any distance whatever. They would have died early without operation and would not have burdened the statistics of an ambulance placed a little further in the rear. While its statistics have not benefited by delay, by transportation, or by selection, it is true that the ambulance benefited from its proximity to the trenches, which not only permitted the patient to be brought promptly to the surgeon, but also avoided the evil results to a patient with a perforated intestine from long transportation, which would have permitted the diffusion of fecal matter in the abdomen. Operation does not seem to have directly caused death in any case. It was perhaps useless in three cases, but it saved at least eleven or twelve lives. The question of early operation depends entirely on the character of the battle, possibility of relief, and the rapidity and suitability of the means of transportation.

In an effort to overcome unwholesome, unsatisfactory operative surroundings, and to insure early operations under suitable conditions, with proper provision for after treatment, the heads of many of the different Medical Army Corps have decided that the motor operating theater is of the most value.

These theaters can be taken immediately on the firing line and equipped with all the modern conveniences, being of extreme advantage in rupture of the liver, severed hepatic, iliac, renal, and other arteries, involvements of the small intestines, and dum-dum wounds of the colon, all of which would not and could not have survived were it necessary to transport them for any distance.

Such a theater should carry all of its personnel, be compact, thoroughly dust-, dirt-, and wind-proof; in fact, in other words, a complete thoroughly equipped operating-room upon wheels. It is a highly convenient and necessary item and can be taken almost anywhere that its requirements are most needed. The fact that it can be made of a reasonable size and still be of a reasonable price makes it of more value. To describe fully the pattern which I found of best service and compactness: The body is 10 feet long and 6 feet 6 inches wide; it contains a cab 3 feet long and 6 feet 6 inches wide, the height of both being 7 feet; it weighs, including equipment and five persons, about 2½ tons, and has suitable arrangements regarding steering facilities and a clear space of at least 2 feet 9 inches and more if required available for a stretcher way. All boiling, sterilizing, and wash drying is done in the cab or partly outside of the theater by paraffin burners.

The cab is separated by an air-sliding door from the body of the theater, which thus eliminates all gases, a most important point as regards the efficiency of the personnel. Cold sterile water is obtained in the body of the theater roof either by tabloid hypochlorite in fifteen minutes or by filling the four vessels carried from the boiler. The cab contains two large closets, providing for towels, gowns, wool, gauze, bandages, and instruments. In addition a minimum of 16 full-sized drum shelves and one drum stool containing plaster of paris if needed. Seven cubic feet are available under the operating table if desired and the above-mentioned water tanks, two in number, carry twenty gallons each. If necessary, electric light can be run for six hours off the accumulators, a minimum time of fifteen minutes being available for recharging from the engine between operations. Ventilation is obtained by windows and an electric fan. The tail board is arranged ingeniously so that the outer surface is always outside and dirt, mud, and filth are not tipped into the theater when it is closed up. Regulation ambulance canvas covers it completely when traveling. The chassis may consist of any 30 to 40 horsepower motor in the market. So long as supplies arrive regularly the theater can be kept in use to deal with grave cases of abdominal, head, and limb injuries. The cost is nominal and the equipment varies as to its proficiency. Although these operative field theaters are known to be of estimable value in the treatment of the wounded, not one has, up to this time, existed in the medical department of the United States army. It has been but recently that Major Williams, U. S. A. M. C. supply depot, has endeavored to devise and construct such a theater. He will probably realize its efficiency and necessity to the medical corps in times of war.

POSTOPERATIVE TREATMENT OF PEPTIC ULCER AND CHOLECYSTITIS.

By J. RUSSELL VERBRYCKE, JR., M.D.,

WASHINGTON, D. C.

INSTRUCTOR IN GASTROENTEROLOGY IN THE MEDICAL DEPARTMENT OF GEORGETOWN UNIVERSITY, MEMBER OF THE HOSPITAL STAFF, VISITING GASTROENTEROLOGIST TO THE WASHINGTON ASYLUM HOSPITAL, WASHINGTON, D. C.

THE writer was stimulated to prepare this paper by observation of the bad results often following operations, generally skillfully performed, when after-treatment based on a consideration of the etiology and pathogenesis might have produced better results. When the skilled surgeon and trained internist combine forces in the treatment of these patients there should be an improvement.

We shall consider first the postoperative treatment of ulcer of the stomach and duodenum. We do not know absolutely the cause of ulcer. There can be little doubt, however, that it is a septic infarct. We may never know why some people are prone to the affection. It is probably a lowered resistance to a certain organism, not a specific one; and where a small infarct of one of the other organs might readily heal, when it occurs in the duodenum or stomach and the necrotic area is digested by the action of the gastric juice, it may be kept from healing. Another theory to be considered is Rosenow's specificity of localization. Rosenow believes that certain strains of organisms have a specific affinity for certain organs, and some of our experiments would tend to confirm this.

*President's address before the Hippocrates Society, Washington, D. C., May 13, 1915.

Often the original focus of infection can be demonstrated as alveolar abscess or diseased tonsils. At times the condition is secondary to ileal stasis. In fact, it is stated that Lane goes so far as to recommend operation for the latter condition and not the ulcer. There are too many ulcers occurring after rheumatism to be purely coincident, and so on with other conditions. Organisms can be recovered from the majority of ulcers. Rosenow demonstrated this fact last year by means of his technique of macerating the tissues and culturing.

Before Rosenow's report, I, with the collaboration of Stimmel of the Army Medical School, had been working at the same thing for some months, and we had, in addition to making cultures, demonstrated the presence of organisms in situ imbedded in the ulcer. We have slides showing organisms in all parts of the ulcer, some being completely surrounded by fibrous tissue in the scar formation. The organisms may be of different sorts, probably most often streptococci and less often staphylococci and others.

Therefore our first step in the postoperative treatment begins at operation. Whenever possible the ulcer should be excised, kept from contamination, and examined for organisms from which autogenous vaccines can be prepared and administered during convalescence. I have secured some very remarkable results in the treatment of ulcer medically by vaccine, but here we are handicapped by not knowing definitely with what organism we are dealing. Results should be more constant under these circumstances where it is isolated. The vaccine therapy will be considered more in detail later.

There can be no routine treatment after operation for ulcer. We must treat the individual patient, bearing in mind the possible cause of the trouble, the character, and position of the ulcer found at operation, and the nature of the operation itself.

Whenever possible we know that it is best to excise the ulcer. When this has been done the after-treatment is much more simple than otherwise. Often a posterior gastroenterostomy has been done at the same time. I believe this is usually unnecessary and should be done only to meet some special indication.

In these cases of excision we have simply (1) to regulate the diet for from 10 to 14 days; (2) to administer atropine or belladonna to prevent spastic contraction of the pylorus which would tend to produce further trouble; (3) to make and administer autogenous vaccine; (4) to avoid irritating purgatives; (5) before the patient is discharged to make search for the original focus if it has not already been located and take steps to eliminate it, and (6) to instruct patients to report at least every two months for a year with a specimen of stool, while on meat free diet for 3 days, to be examined for occult blood.

Diet.—Two hours after the anesthetic nausea has ceased the patient may start taking water. In fact I believe it not unwise to begin even earlier to wash the ether out of the stomach, as by lavage, if the patient vomits, for the reaching is not as bad as that occurring on an empty stomach. When the water is well borne we may start with albumins, not too acid, followed by buttermilk. It is best not to proceed further with the diet until the postoperative gas has subsided. After this a soft diet with plenty of milk can be ordered through the second week, avoiding strong acids, spices, and extractives. After the second week, at all events, firm union must have

occurred in the stomach wound and a full diet may be allowed, omitting only the most indigestible articles. Most ulcer patients have been pretty heavy meat eaters. They should be cautioned against eating meat more often than once a day and then only in moderate amount.

The administration of atropine or belladonna serves two useful purposes, first helping to diminish the flow of acid, and secondly, by its action on the nervous system, relaxing pylorospasm which might occur from the irritation of the wound in the stomach and so tend to produce another ulcer. The first doses should be administered with the morphine which is given hypodermically for postoperative pain. Later tincture of belladonna may be given by mouth for several weeks.

Irritating purgatives should be avoided. The bowels had best be left alone for several days as a rule. Postoperative gas is usually pretty troublesome as a result of the handling of the viscera. This is controlled by the passage of the rectal tube, followed later if necessary by saline or perhaps purgative enemata. If anything is given by mouth it should be mild salines, preferably Carlsbad salts.

The Use of Vaccines.—This work is yet in its infancy. To the best of my knowledge I believe that I was the first to make systematic use of vaccines in the medical treatment of gastric and duodenal ulcer, about 18 months ago. I have during that time used them in many cases though in but few operative cases. The results have been so good in some cases that I am still persisting in their use. One of my patients who had a recurrence a few months after operation for duodenal ulcer was apparently completely cured after four injections.

The search for the focus of infection is unfortunately not always attended with success. It is our duty, however, to try and eliminate all factors which might further the production of another ulcer or prevent the healing of the one operated upon, providing it has not been excised.

In regard to the patients reporting at intervals for examination of the stool, it may be said that occult blood often appears in the stool, from a recurrence of ulceration, weeks before symptoms declare themselves. I am aware that many observers do not attach so much importance to the occult blood test as I, but after an experience of over one thousand tests I am firmly convinced of the great value under proper precautions. To secure reliable statistics as to results we should use as great care in determining the cure as in making the original diagnosis. For at least a year the result should be noted "Apparently Cured". We know that the ultimate results in ulcer cases, generally speaking, are deplorable. Younger surgeons are much more enthusiastic than those of greater experience. Some think it sufficient to say "Ulcer? Then let's operate and cure it." It would be a blessing if we could be so sure, but as a matter of fact, Joslin's statistics, presented at Atlantic City in 1914, cause us to pause and think. In his series of cases treated at the Massachusetts General Hospital and in private practice but 39 per cent. of those operated upon were well after 15 years.

In view of these failures it has impressed me forcibly that there is need for something new in the treatment of ulcer, a getting down to basic etiological factors; and I believe that the practice of the measures indicated above will cause us to come a little closer to our goal of all cures.

I have gone into the postoperative treatment after

excision rather fully and will in consideration of other operations simply give points of difference.

The treatment after gastroenterostomy varies somewhat according to the location of the ulcer. In the first place, it may be stated that gastroenterostomy is not in any sense of the word a curative procedure. It simply creates certain conditions which favor nature's healing of ulcers in certain locations.

In duodenal ulcer with closure of the pylorus and gastroenterostomy little else need be done. Neither food nor acid touches the ulcer and so ideal rest is secured. The diet is that of any operative case. The patient should be cautioned, however, against violent exercise and should be instructed to lead a simple quiet life for some weeks so that the ulcer may have a chance to heal, although healing will not always take place. Symptoms may be absent but examination reveals that the ulcer is still open and oozing blood. I have had three cases of duodenal ulcer in which marked symptoms have recurred after operation. There is then little to be done except to try another operation or a medical treatment. We should always try the vaccine treatment, although we may not hit the organism right. The writer's vaccine is a special stock made of a number of strains of streptococci isolated from ulcer and pyorrhea cases. If no result is obtained, or there is no sign of a local reaction to fairly good-sized doses, the presumption is that we have not hit the right organism and a combination of colon and staphylococci is then used. This may be said to be hit-or-miss therapy, but enough cases have been affected almost miraculously to prove conclusively to my mind that proper vaccine for the individual case is going to be a great help.

After gastroenterostomy for ulcer at the pylorus we must use greater care in the postoperative treatment. Food and acid can still come in contact with the ulcer. The operation has simply allowed better drainage, eliminated in large measure bad effects from pylorospasm, and has allowed the alkaline intestinal juice to enter the stomach. It used to be the practice of some surgeons to allow the patient to eat anything after he recovered from the immediate effects of the operation and to be up and about after ten days or two weeks. This was horrible practice, though many patients did get relief from symptoms and gained in weight. These patients should be treated after operation medically for ulcer just as strictly as if operation had not been performed. The diet for the first three days should be the same as that outlined above for excision, but after that time should progress differently. Milk and barley water should be used exclusively for at least ten days, after which eggs, custard, butter, olive oil, cereal, gruels, and crackers are gradually added until finally at the end of three weeks the patient is on a soft, unirritating, non-acid-forming but very nutritious diet, which is kept up for several weeks more. Strong acids, spices, and broths should be prohibited for a year. These patients have usually been pretty heavy meat eaters. They should be cautioned against eating meat more often than once a day.

Bismuth or silver nitrate should be administered three times a day before meals from about the third day for several weeks, and liberal amounts of alkalis after meals. The patient should not sit up for from two to three weeks, and then gradually.

What has been said of ulcer at the pylorus is

even more true of ulcer of the lesser curvature. Where the ulcer has not been excised the combined resources of medicine and surgery are very often unavailing.

Not only does the location of the ulcer influence the after-treatment, but also the conditions found at operation. A large callous ulcer of many years' duration, if ever curable by rest will certainly take longer than a small nonindurated one.

Perforated ulcers naturally demand certain other treatment which comes purely under the domain of the surgeon, such as (in acute cases) the Murphy salt solution and the Fowler position, which need not be considered here. For some reason perforated ulcers seem to tend to heal without much difficulty after the perforation is closed. The medical treatment after the operation will fall under one of the above headings. One of my cases of perforated ulcer was hastened greatly in convalescence and, in fact, the scales seemed to be turned from impending death from toxemia to recovery through the use of vaccine.

Postoperative Treatment of Cholecystitis.—Ordinarily results in gall-bladder cases may be said to be decidedly better than those following operations for ulcer; however, the number of secondary operations required and the not inconsiderable number having a continuance or recurrence of trouble after drainage or even removal of the gall-bladder would indicate that there is room for improvement in our treatment. The writer believes that the reason for many of the poor results lies in the fact that the original factors which caused the trouble have not been influenced.

A brief consideration of the etiology of gallstones may be in order. It is well known that the small stones may be either hepatic or cystic in origin, so that removal of the gall-bladder will not guarantee against future trouble, although it tends to minimize the chance, since most stones probably attain their size in the gall-bladder.

Since 1885 the bacterial origin of gallstones has been recognized. We know that the three organisms most commonly causing trouble are the typhoid bacillus, colon bacillus, and streptococcus. It seems reasonable to suppose that organisms infecting the biliary tract constitute the most essential factor in the production of stones. Cultures of broken-up stones will often demonstrate the presence of viable organisms at the very center. There are probably other factors of which we are ignorant, but biliary stasis and inspissation of the bile, while probably not sufficient *per se* to produce stones, must be among the predisposing factors. When the nucleus is once started the stone grows perfectly naturally by the deposit of more salts. The salts may be of various kinds, but in the case of cholesterin we have probably another factor added which is some disturbance of fat metabolism, perhaps of two varieties, either from excessive ingestion of fat and too little exercise or from a deficiency of thyroid secretion. We do know that a considerable number of gallstone cases are to be found in the over stout.

Some years ago I devised a medical treatment for certain forms of cholecystitis, one of the principal features of which is the reduction to a minimum of the fat ingested. This was based on clinical grounds alone, but during the past few weeks I have learned that Epstein of New York has found that the cholesterin content of the blood can be modified by restriction of the fats and good results have been obtained in gall-bladder cases, in his experience

also, by this procedure. Much work has also been done by Henes, who has shown a marked increase in the cholesterol content of the blood in gallstone disease.

From a consideration of the foregoing it would appear evident that we have not done enough when we remove the gallstones and drain the gall-bladder, or even when we remove the gall-bladder if the same conditions which originally caused the trouble still obtain.

How long the gall-bladder should be drained and other purely surgical questions will not be here considered. We will merely consider the medical after-treatment in these cases.

I will describe my treatment. I believe that no other form of diet will suffice, but in other details there may be other means just as effective if based on etiologic grounds.

The patient should have an individual diet list based upon the condition of digestion and the weight, but in all cases the fat should be restricted to a greater degree than the other food products. In the obese fat reduction should be practically absolute for a time so that the patient may use up some of his own. I believe that some control should be kept over the fat ingested for at least a year. If the bowels tend to become sluggish from the absence of fats mineral oil which lubricates without being digested may be given.

Next to the fats the carbohydrates should be restricted. Judgment is required in determining how far this may be safely carried. Proteins are allowed in sufficient quantity to maintain nitrogenous equilibrium. All of the vegetables that are desired may be taken and also fruit, provided the chemical condition of the stomach does not contraindicate.

The bowels should be kept open. Plenty of water will help with the addition of Carlsbad Sprudel salts when required.

After convalescence exercise should be prescribed. Outdoor exercises, such as walking and golf, are especially desirable, as also special abdominal exercises which tend to reduce the fat, stimulate the circulation, and correct sluggishness of the biliary as well as the whole digestive tract.

There are two drugs used in my medical treatment for cholecystitis and I believe the same treatment is indicated after operation; then an hexamethylenamine and bile salts. If I remember correctly, Crowe of Baltimore was the first to recommend large doses of hexamethylenamine in gall-bladder affections and I then incorporated it in my treatment. Recently considerable doubt has arisen as to the efficacy of this drug in various parts of the body and a number of experiments would seem to show that it is useless, yet the clinical results from the treatment as a whole have been so good that I have hesitated about dropping this part of it. Postoperatively 15 grains a day should be given for a number of months, unless contraindicated by some untoward action.

The bile salts act by keeping the biliary secretions more fluid. One five-grain tablet of sodium glycocholate or its equivalent two or three times a day should be administered for some months.

Thyroid extract for its action on fat metabolism should be used temporarily in the cases in which it would seem that there was deficiency of thyroid secretions with poor oxidation. Small doses should be used at first and close attention be paid to the blood pressure and pulse.

Cases resulting from a previous typhoid infection

should, perhaps, have several injections of typhoid bacterin. I would advocate in other cases the administration of a stock mixture of streptococci and colon bacillus with a view to the prevention of further trouble in the gall-bladder and the sequelæ which often follow, such as appendicitis and ulcer.

The attempt to eliminate any causative focus of infection is as important in the gall-bladder cases as in ulcer.

The majority of patients do well without such particular attention being paid to the after treatment, but we are interested in the others who have future trouble; as we have no means of determining which these will be, it would seem advisable to give to all the advantage of such a treatment, based upon etiological grounds, which can at least do no harm and which I feel would give infinitely better end-results to the operative procedures in these cases.

THE ROCHESTER

SOME CLINICAL PHASES OF THE VASO-MOTOR NEUROSES.

By WILLIS E. HARTSHORN, M.D.,

NEW HAVEN, CONN.

IN the routine examination of patients there are certain physical conditions noted at times which are atypical and difficult to associate with any distinct pathological lesion. It is probably true that recent legislation affecting compensation has multiplied this class of cases. To determine the exact status of these individuals from a clinical standpoint is difficult without the most thorough physical examinations and careful observation over a considerable period. The following interesting case was referred recently for examination:

CASE I.—Patient G. M., aged 27, works in a steel mill. In October, 1914, while wiping his hands on waste he felt a sharp prick in the second finger of the right hand. He thought at the time that a small piece of steel had entered the finger, so went to his physician, who thoroughly cleaned the wound and removed all fragments of metal. Moderate swelling of the finger and hand followed. This gradually subsided. He has, however, been on short time, receiving compensation, during the past eight months owing to the fact that as soon as he attempts to do heavy work the forearm and hand become swollen. An interesting feature of this, however, is the fact that this swelling has never been observed by the family physician, as it occurred only during his working hours. The patient had appendicitis three years ago. Was married at twenty-one years of age. No venereal history. Two children both well. Not alcoholic. Physical examination May 17, 1915. Patient well developed and nourished. Appears very excitable. Hands have a distinct tremor when outstretched. There is a decided nervous diathesis. Circulation in both upper extremities seems sluggish. There is no sign of swelling in either. Sensory and motor reflexes are normal. The urine contains neither sugar nor albumin. Blood pressure is 150. Abdominal examination negative. Knee jerks exaggerated. Marked urticarial rash. X-ray negative. The patient was advised that the condition was a nervous disorder, not of a serious nature, and that the free use of the extremity would have a favorable effect on the swelling of the forearm and hand. Since then he has reported once for examination and states that there is no more edema or pain and that he is able to do his work very much better. Just how much the desire for compensation had to do with this case would be interesting to determine.

CASE II.—A woman 45 years of age, well developed and well nourished. Generally healthy. Not neurotic. When first seen she stated that at intervals she was troubled with sudden swelling of the tongue, which made it difficult to swallow and also interfered with her speech. Examination shows the tongue to be markedly swollen and slightly sensitive to pressure. Teeth in good condition; Riggs' disease latent. Peculiar numbness of the tongue complained of. This patient

reported on the next day that the swelling had disappeared. Six months later she again noticed a similar swelling of the tongue on arising in the morning. At this time she was not in good physical condition and had endured considerable nervous strain. The swelling was associated with constipation and urticaria. No pain or discomfort except from the size of the tongue. This reached the normal condition again within a few days. There has been no recurrence of the symptoms since that time.

In the consideration of the two cases noted the following points are worthy of mention: (1) Transient edema occurs under certain definite conditions. (2) There is a nervous diathesis. (3) There are associated urticarial symptoms often of the giant type or other skin eruptions. (4) A number of the cases give a history of a very chronic venereal infection which has depleted the nervous system. (5) Abdominal symptoms are common, either acute abdominal pain associated with constipation or a previous history of intestinal stasis. The vasoneuroses present a most interesting group. Under this heading should be classed: (1) Angioneurotic edema with its associated skin lesions; (2) erythromelalgia or red neuralgia; (3) endarteritis obliterans or thromboangiitis obliterans of Buerger; (4) intermittent lameness or claudication, the crural angina of Walton; (5) epidermal changes and peripheral sensory neuroses of the trophic type.

Angioneurotic edema is a condition with which familiarity is important, otherwise the cause of the edema may puzzle the physician as well as it does the patient. These cases may be called comparatively rare. The symptom complex presents sudden swelling of either an extremity, the genitalia, the face, the tongue, or the lips. This will continue for a length of time varying in different instances; at times it is very transient, at other periods very difficult to relieve.

Weil reports five cases with the following sequence: (1) Edema of the scrotum. Excitation chronic venereal infection. (2) Edema of the lips and vulva. Erythematous eruption on the arms and fingers, associated with abdominal pain localized about the gall-bladder. Operation revealed hourglass gall-bladder with stones. (3) Edema of the lips. Associated abdominal attack simulated appendicitis. (4) Edema of the genitalia. Associated lesions were abdominal pain, Von Recklinghausen's disease (multiple neurofibromatosis), tuberculosis, mental deficiency, and neuroses of varying character. In practically all of the cases reported we have the combination of the edema associated with the skin lesions usually of the urticarial type with intense itching, gastrointestinal symptoms, and various nervous manifestations. It is difficult to decide on the exact etiology. Its occurrence reported in successive generations suggests a possible hereditary origin. Like urticaria, with which it is so closely related, angioneurotic edema may be due to the absorption of toxic poisons from the intestinal track. One very interesting case occurs to the writer in which 1,500 units of tetanus antitoxin was administered as an immunizing dose following a punctured wound. There occurred in a few days an intense edema of the extremities which gradually extended to other parts of the body, presenting a severe complication. This patient was very seriously affected and found it necessary to give up his regular vocation for about ten days. Only recently a patient with a marked nervous diathesis recovering from a grippe infection noted a sudden swelling of the right foot and

ankle. This extended up the leg, causing considerable discomfort. It was associated with small red papules and elevated areas of a grayish character, several 5 or 6 cm. in diameter. Herpes zoster was eliminated by the lack of pain and the general distribution of the eruption rather than along the nerve trunks. The swelling disappeared along with the other clinical signs in a few days. The general appearance of the limb accentuated the nervous symptoms, as the patient felt sure she was suffering from blood poisoning. No swelling of the other extremity occurred.

What can be learned regarding the pathology of angioneurotic edema indicates that it is closely associated with urticaria edematosa and is a vasomotor disturbance of the spastic type affecting both the capillaries and the lymph channels, causing a paralysis of the vasoconstrictors or irritation of the vasodilators, and is produced according to Auspitz, by reflex irritation.

It is a peculiar fact noted by a number of observers that the exact time and place at which the swelling will recur can be accurately stated by the patient in some instances. This would again seem to indicate a closely associated neurotic element.

In this connection should be mentioned Raynaud's disease which presents a train of clinical events markedly different from angioneurotic edema. Three classical stages are always associated with this lesion: (1) Local syncope; (2) Local asphyxiation; (3) Necrosis with local or symmetrical gangrene. It occurs in neurotic young women as a rule. There may be complete ischemia of a finger of one hand, the so-called dead finger. The time of the attack varies from a few minutes to a few days. The pain is often very severe. Following this the finger and at times the entire hand becomes dusky in color. The sense of touch is diminished. The subsidence is gradual. The attacks may occur at about the same time on successive days. The lower limbs are often affected in the same way as the upper. The asphyxiation noted first in the toes extends gradually to the ankles, and in some cases to the knees. The second stage passes to the third or that of gangrene. This occurs either in the tip of a finger or toe and may involve gradually a still larger proportion of an extremity. It is very apt to be symmetrical. The fingers and toes are particularly liable to be affected. The nose and ears are also at times attacked. The pathology of the condition is not well understood. Vascular spasm of a vasomotor origin undoubtedly plays an important part in the etiology. Osler states that there are two totally different forms of congestion which may be shown in adjacent fingers: one may be swollen, of a vivid red color, extremely hot; the adjacent finger may be equally swollen, absolutely cyanotic, and stone cold.

Erythromelalgia or the red neuralgia should be mentioned as a probable vasomotor affection. Described first by Weir Mitchell in 1872 as a peripheral neuritis, it has been associated by various writers as a vasomotor neurosis or due to irritation in the cells of the ventral horns of the cord. The definite origin has not been determined. The disease is rare. The symptoms are quite characteristic. The lower limbs are more often affected than the upper. There is burning pain in the foot, which gradually extends to the leg accompanied with swelling and a dull reddish blush. There is considerable pain, which is worse on standing. There is local elevation of temperature. These

symptoms gradually subside, but the foot remains for some time of a purplish color. The burning pain and the red flush are really the most important symptoms. The disease is usually asymmetrical. To distinguish it from Raynaud's, Weir Mitchell emphasized the color play, that is the bright reddish tinge gradually merging into the purplish tint. The symptoms may persist for years in varying degrees. There is no gangrene. Sensation is preserved. While Raynaud's disease begins with anemia, in erythromelalgia, or the painful red extremity as it is frequently called, there is marked arterial pulsation. Osler quotes Weir Mitchell as reporting the following case in the *Philadelphia Medical Times*, Nov. 23, 1872. A sailor, aged 40, who after an African fever began to have "dull, heavy pains at first in the left and soon in the right foot. There was no swelling at first. When at rest he was comfortable and the feet were not painful. After walking the feet were swollen. They scarcely pitted on pressure, but were purple with congestion; the veins were everywhere singularly enlarged, and the arteries throbbed visibly. The whole foot was said to be aching and burning."

Another curious condition which should be associated with those discussed previously is intermittent lameness or claudication. The etiology so far as known suggests a spasm of the arterioles due to a defect in the vasomotor control. This is usually indicative of a commencing sclerosis in the circulatory system. The term intermittent claudication is one employed by French veterinarians to indicate thrombosis of the iliac arteries in horses and has been recognized by them for a good many years. As a disease in man the condition was first described by Charcot in 1857. The symptoms develop somewhat as follows: After walking for some time there is first a marked weakness in the muscle of the lower extremity. This is soon followed by sudden cramps, which are so persistent as to compel rest. After a period of repose relief is experienced and the circulatory balance is regained. Attacks usually recur.

Endarteritis obliterans, while differing markedly in its origin from the conditions we have discussed, should be here mentioned as it presents a picture similar in some respects. It frequently occurs in Russian Jews addicted to the cigarette habit. This type of lesion has been termed thromboangiitis obliterans by Buerger,³ who in a recent article considers it an infectious disease. Endarteritis obliterans is an entirely distinct condition from senile gangrene, which belongs to the arterial sclerosis of old age. It often occurs comparatively early in life and frequently follows as a sequence of the various systemic infections. Attention should be called to the fact that it also develops insidiously without any relation to any other pathological condition. Its onset is marked by pain in the toes and lower extremities. Usually this is unilateral and very persistent, causing the patient so much distress that he will spare no effort to secure relief, submitting even to amputation of the extremity. Next to the pain is noted the dusky color of the extremity with lack of pulsation in the dorsalis pedis and posterior tibial arteries. This passes on to a gangrene which, owing to its gradual extension, requires amputation; but this is often unsatisfactory, as the vessels continue to become thrombosed above the stump. Arteritis obliterans should be differentiated from Raynaud's disease by the

fact that the onset is very gradual; men are usually affected, and there is no neurotic history. The three typical stages which follow as a sequence in Raynaud's disease are missing, that is, anemia, congestion, necrosis. It is asymmetrical. From senile gangrene by the age of the patient, the condition of the arteries in other parts of the body at a distance from the area affected, referring by this to evidence of arterial sclerosis.

The circulatory affection in thromboangiitis obliterans is a very serious one, amputation even, unless far above the site of the lesion, failing to give permanent relief. There is a constant tendency for recurrence about the end of the stump. The vessels show distinct pathological changes pointing toward the infectious nature of the disease. There is thickening of the intima, and Buerger states in his description that "the arteries and veins are filled with infective material. In many the walls are definitely infiltrated with leucocytes and the lumen completely occluded with red clots in which certain foci spoken of as military giant-celled foci make a striking picture. The purulent areas are invaded by leucocytes from the media and adventitia, which are not merely agglutinated and derived from the intravascular blood." This condition cannot well be mistaken; at the same time careful attention must be given to the history and symptoms in order to make the differential diagnosis. Diseases of the arteries are always the most difficult of the chronic lesions to combat. Arteriovenous anastomosis has been attempted without satisfactory results in arteritis obliterans and the problem of treatment up to the present time remains unsolved.

Other conditions which cause lesions involving the nutrition of the extremities can be traced to diabetes, chronic nephritis, the various lesions of the heart, and malnutrition. As they have a definite origin they do not present the obscure etiology of the vasomotor lesions and therefore respond more readily to treatment applicable to their especial needs.

In diabetic gangrene we have a condition based on the abnormal condition of the nutritive elements. It might be considered, owing to certain peculiar features, on the border line between the constitutional and the endarteritis associated with a peripheral neuritis. For this reason it perhaps deserves brief mention here. The onset follows trauma of some sort such as a bruise or blow. It commences as a small patch or gangrenous area without pain and without the usual odor which attends gangrene or other types. It is frequently accompanied with or preceded by other trophic disturbances. Diabetic gangrene is amenable to diabetic treatment if taken early. The patient, if neglected, will die from a combination of toxemia and diabetic coma.

Differential diagnosis is very necessary in vasomotor affections. A routine examination of the urine is a most important feature, in every case suggesting circulatory disturbance.

SHAKESPEAREAN CONCEPTIONS OF SOME MEDICAL TOPICS.

BY J. A. HAGEMANN, M.D.,
PITTSBURGH, PA.

IF we ponder the fact that Shakespeare wrote his immortal productions during the period when medicine had scarcely emerged from the realm of superstition, when the "barber-surgeons," whose dual function comprised the shaving of priests' tonsures and the performing of surgical operations, were universally held in contempt, we are led to the conclusion that his knowledge of medical themes was not only matchless, but that in spots it was almost predictive. From the days of Hippocrates, 470-361 B. C., and Galen, 131-201 A. D., no revolutionary medical progress had taken place. True, Paul of Aegina, Bouvé, and Rogerius had advocated giving nature a chance; Guy de Chauliac and Henri de Mondeville had published surgical works during the fourteenth century, which remained unrivaled textbooks for two hundred years, but the rank and file of the medical profession, if we can so dignify the healers of those days, were sadly incompetent. Shakespeare was born the year following Vesalius' death, and Ambrose Paré was flourishing while the youthful bard of Avon courted Ann Hathaway. Perhaps the elevating influence of these men penetrated the atmosphere of contumely which encompassed men practising the healing art and made a figurative rift in the clouds, through which Shakespeare was able to discern, more clearly than his contemporaries, the intrinsic worth of the honorable physician. Bacon, in "Hudibras," and Cervantes, in "Don Quixote," had seen fit to treat medical subjects flippantly, if not scoffingly, and the spirit instigated by them seems to have the doubtful quality of immortality, if one may judge from the attitude of many succeeding authors, even to the present day.

Although not a character in the play, Gerard de Narbon, a fictional deceased physician, is reminiscently commended. In "All's Well that Ends Well," the Countess of Rousillon pays him extravagant tribute when she says his "skill was almost as great as his honesty; had it stretched so far 'twould have made nature immortal, and death should have play for lack of work. Would, for the King's sake he were living! I think it would be the death of the King's disease." To which the aged Lord Lafew, acquiescing, replies: "He was excellent, indeed, madam: the King very lately spoke of him admiringly and mourningly: he was skillful enough to have lived still, if knowledge could be set up against mortality." Shakespeare's impression of the guiding star which allures the conscientious physician is admirably voiced by Cerimon, a lord of Ephesus, one of the characters in *Pericles*, who says: "'Tis known, I ever have studied physic, through which secret art, by turning o'er authorities, I have—together with my practice—made familiar to me and to my aid the blest infusions that dwell in vegetives, in metals, stones; and I can speak of the disturbance that nature works, and of her cures: which doth give me a more content in course of true delight than to be thirsty after tottering honor, or tie my treasure up in silken bags, to please the fool and death."

The Second Gentleman, in making reply thereto, shares the popular misconception regarding communal gratitude which is presumed to be one of the emoluments of the philanthropic physician, but

which is encountered sporadically, rather than epidemically, for he answers: "Your honor has through Ephesus pour'd forth your charity, and hundreds call themselves your creatures, who by you have been restor'd: and not your knowledge, your personal pain, but even your purse, still open, hath built Lord Cerimon such strong renown as time shall never raze."

In *Macbeth* a nice question of ethics is raised. The doctor, who is discussing the somnambulism of Lady Macbeth with one of her waiting gentlewomen, insists upon learning the trend of her babblement; and when the gentlewoman refuses to be disloyal to her mistress by repeating the unconsciously spoken words, he urges: "you may to me: and 'tis most meet you should." Evidently he is seeking enlightenment to aid him in arriving at the etiology of the illustrious patient's malady. Before the ethics of this delicate problem is determined, the lady herself enters upon the scene, and the physician has opportunity to make his own observations. Evidently, however, he feels need of the counsel of an alienist, for he frankly confesses: "This disease is beyond my practice." He fully appreciates the element of psychic disturbances in the causation of mental alienation, for he vouchsafes the opinion that "unnatural deeds do breed unnatural troubles: infected minds to their deaf pillows will discharge their secrets." How consistently the mental derangements of Shakespeare's mad characters are delineated! This must ever be a source of gratification to the reader or spectator of his plays. *Hamlet*, *Ophelia*, *King Lear*—all cameos in magnificent settings!

An edifying example of how well Shakespeare recognized the psychic effect of physical indisposition is afforded us by *King Lear*, who, tempestuously inclined to transmit an offensive message to the duke of Cornwall, reconsiders his impetuosity, and exclaims: "No, but not yet:—may be he is not well: Infirmity doth still neglect all office whereto our health is bound; we're not ourselves when nature, being oppress'd, commands the mind to suffer with the body: I'll forbear.—" Conversely, Shakespeare was cognizant of the baneful physical effects of evil frames of mind or of lurid mental impressions. Iago, having aroused jealousy in the mind of Othello, says: "Dangerous conceits are, in their natures, poisons, which at first are scarce found to distaste, but, with a little act upon the blood burn like the mines of sulphur." In "The Winter's Tale," Leontes, king of Sicilia, admirably expresses the physical result of a nauseating mental process when he states that "There may be in the cup a spider steep'd, and one may drink, depart, and yet partake no venom; for his knowledge is not infected; but if one present th' abhorrent ingredient to his eye, make known how he hath drunk, he cracks his gorge, his sides with violent hefts." Of the beneficial effect of cheerfulness the author was equally aware. In "The Taming of the Shrew," a servant announces to Sly: "Your honor's players, hearing your amendment, are come to play a pleasant comedy: for so your doctors hold it very meet, seeing too much sadness had congeal'd your blood, and melancholy is the nurse of frenzy: Therefore they thought it good you hear a play, and frame your mind to mirth, and merriment, which bars a thousand harms and lengthens life."

In the second part of "King Henry IV" there occurs a lucid description of aphasia. Sir John

Falstaff, having been summoned before the Lord Chief Justice of the King's Bench, evades the question at issue by stubbornly dwelling on "his highness' whoreson apoplexy." His characterization of the significant mental hebetude which afflicts the survivor of an apoplectic attack is admirable, for he says: "This apoplexy is, as I take it, a kind of lethargy, an't please your lordship; a kind of sleeping in the blood, a whoreson tingling . . . It hath its original from much grief, from study, and perturbation of the brain: I have read the cause of his effects in Galen; it is a kind of deafness." He might almost have coined our modern expression "word-blindness." Of course, he is in error as to the etiology of apoplexy, but considering the fact that Galen is cited as his authority, and that dissection was performed only upon the cadavers of animals, his conception of the ailment is not to be harshly criticised.

The cherished family prescription, always secret, and always proven infallible by some ancestor, is familiar to every practising physician. Hence, we experience no astonishment at the statement of Helen, in "All's Well that Ends Well": "You know my father left me some prescriptions of rare and prov'd effects, such as his reading and manifold experience had collected for general sovereignty: and that he will'd me in heedfullest reservation to bestow them . . . Amongst the rest, there is a remedy, approv'd, set down, to cure the desperate languishings whereof the King is rendered lost." Although the King's physicians have persuaded him that any treatment would be futile, Helen proffers her kindly offices, and overcoming the King's expostulations, assures him that in two days he shall be restored to health. It goes without saying that the King recovers within the allotted time. We frequently see equally marvelous histrionic accomplishments on the stages of our modern theaters. Recognition of the circumstance that some diseases end by crisis is indicated by Cardinal Pandulph, in "King John," when he says: "Before the curing of a strong disease, even in the instant of repair and health, the fit is strongest; evils that take leave, on their departure most of all show evil."

The occasional necessity of employing heroic measures, is tersely expressed by the King, in "Hamlet," when he states that "Diseases desperate grown by desperate appliance are relieved, or not at all."

Every physician can cite examples of scant courtesy being accorded him when he has had to deny some unreasonable or preposterous request. We find an accordant case when Macbeth, being informed by the doctor that Lady Macbeth is "not so sick . . . as she is troubled with thick-coming fancies, that keep her from her rest," demands that the doctor "cure her of that; can'st thou not minister to a mind diseas'd; pluck from the memory a rooted sorrow; raze out the written troubles of the brain; and with some sweet oblivious antidote cleanse the stuff'd bosom of the perilous stuff which weighs upon the heart?"

When told that this is not feasible, he impatiently exclaims: "Throw physic to the dogs,—I'll none of it." We cannot help but sympathize with the poor doctor, when he mournfully soliloquizes: "Were I from Dunsinane away and clear, profit again should hardly draw me here."

In "All's Well that Ends Well," young Bertram, Count of Rousillon, solicitously and artlessly in-

quires of the aged Lafeu: "What is it, my good lord, the King languishes of?" To which Lafeu replies: "A fistula, my lord." Young Bertram makes answer: "I heard not of it before." But the old Lord Lafeu, having come into proximity with the King, had, perhaps, experienced olfactory evidence of the King's ailment, for he dismisses the subject with a disapproving: "I would it were not notorious."

To write this, Shakespeare must have known that the sphincter's kindly offices are circumvented by intestinal gases where a complete fistula exists.

The homeopathic doctrine, with its "similia similibus curantur," is amazingly foreshadowed in the second part of "King Henry IV," when the Earl of Northumberland says: "In poison there is physic: and these news, having been well, that would have made me sick, being sick, have in some measure made me well: And as the wretch, whose fever-weaken'd joints, like strengthless hinges, buckle under life, impatient of his fit, breaks like a fire out of his keeper's arms; even so my limbs, weaken'd with grief, are thrice themselves."

Atmospheric humidity is recognized as a factor in the etiology of rheumatism, when, in "A Midsummer Night's Dream," Titania, the fairy queen, says: "Therefore the moon, the governess of floods, pale in her anger, washes all the air that rheumatic diseases do abound."

The modern herb-doctor's office, as one still occasionally sees it, could not be more happily described than in the words which Romeo voices when speaking of the apothecary's bazaar: "In his needy shop a tortoise hung, an alligator stuff'd and other skins of ill-shap'd fishes; and about his shelves a beggarly account of empty boxes, green earthen pots, bladders, and musty seeds, remnants of packthread, and old cakes of roses, were thinly scatter'd, to make up a show." Even the Harrison narcotic drug law is foreshadowed, for when Romeo offers a bribe for "a dram of poison," the sorely tempted impecunious apothecary replies: "Such mortal drugs I have: but Mantua's law is death to any he that utters them." Notwithstanding this, he eventually succumbs to the lure of Romeo's gold.

Over the dead bodies of Romeo and Juliet the Friar Laurence tells he had administered to Juliet a sleeping potion which simulated death, yet would lose its force at a time which could be precalculated to a nicety. We note in this, as in some other instances, that Shakespeare's knowledge of the physiological effects of drugs was faulty, or that he adapted them to his histrionic needs.

The persistence of the belief in lunar influence upon the efficiency of vegetable remedies is indicated by Jessica's exclamation in "The Merchant of Venice": "In such a night Medea gather'd the enchanted herbs that did renew old Aeson."

That illusions may be produced by drugs, is lucidly expressed when Macbeth and Banquo have noted how the witches vanished before their open eyes, and Banquo excitedly asks: "Were such things here as we do speak about? Or have we eaten on the insane root that takes the reason prisoner?"

Where the ethics of medicine are to be violated, Shakespeare consistently assigns such rôles to persons who do not rank high in the estimation of their neighbors. The poison which Romeo purchased after offering increasing amounts of gold, was reluctantly supplied by a poor, starved apothecary, while Laertes, in Hamlet, having put poison

upon the blade of his sword, volunteers the information that he "bought an unction of a mountebank." Brabantio, father of Desdemona, in "Othello," attributes the miscegenation of his daughter to drugs supplied by disreputable practitioners, for he says: "She is abus'd, stol'n from me, and corrupted by spells and medicines bought of mountebanks."

These fragmentary extracts from the great dramatist's writings reveal a profound knowledge of medical subjects, and place the physician in the light of being an honorable member of society.

HIGHLAND BUILDING

THE TREATMENT OF DISEASE BY INJECTIONS OF DEEP-SEA WATER AND RADIUM.

BY FRANCIS E. PARK, M.D.,

STONEHAM, MASS.

FOR a period of about fifteen years, René Quinton, the originator of the treatment of disease by injections of deep-sea water, rendered isotonic with the fluids of the body by the addition of spring water, has been carrying on in Paris his great humanitarian work. During this period he has saved thousands of lives, especially those of infants. His method was the object of a great deal of ridicule at first, but as time wore on and the uniformly splendid results of his treatment became known, more and more respect was accorded it, until, at the time I visited him, three years ago, it was customary to find his clinic crowded by physicians from all over Europe.

My attention was drawn to this method by reading a paper written by Dr. Robert Simon of the University of Paris and published in the "International Medical Annual" of 1910. In this such strong and apparently well-substantiated claims were made, that I was induced to try the remedy in a very grave case that was under my care at that time, and with such striking results that I gave it a wide and searching trial, and now, after five years of constant use, can say unhesitatingly that nowhere in medicine, so far as my knowledge goes, have we such a potent, yet safe, general tonic.

In Quinton's book, "L'Eau de Mer, Milieu Organique," there is a very careful analysis and study of the water of the ancient ocean as revealed in deep deposits in mines. The elements revealed there are easily divided into groups. In the first, which contains in bulk more than half of all the others combined, are chlorine and sodium. In the next the amount is very small, but still present in appreciable quantities, and the minerals are sulphur, magnesium, potassium, and calcium. In the next group the amount present is exceedingly minute but still demonstrable chemically, and comprises bromine, silicon, carbon, azote, iron, iodine, manganese, phosphorus, and lithium. Then there is a fourth group, in which the presence of the elements can be determined only by means of the spectroscope; this contains boron, arsenic, copper, silver, gold, zinc, strontium, barium, cesium, rubidium, aluminum, lead, and now later investigations add to the above list, radium.

According to Quinton's researches, all of these elements, in practically the same proportions, have been demonstrated in the body fluids by competent chemists. It was this remarkable coincidence, coupled with his belief that the first living organism was found in the warm waters of the primordial ocean, that led him to the conclusion that if life originated and developed in such a medium, then the

same solution applied to diseased cells, that are in structure similar to the original one, could not fail to be beneficial, by furnishing them a *paulum* which they could easily assimilate, and thus regain their lost energy.

It is hardly the place here to follow the steps by which he was ultimately led to apply his theory in practice; suffice it to say that the evolution occurred, and as a result we find to-day in Paris two large clinics where this work has been carried on for many years in the most careful and scientific manner possible, with all the data for this period open for inspection. The results obtained cover such a wide variety of diseases that one is at once forced back to the very essence of things, in order to reach an adequate explanation of the effects observed, for not only do we see desperately sick enteritis cases recover in a marvelous manner, but various other conditions extending even to chronic skin lesions as psoriasis and eczema.

At the time I visited Professor Quinton, in 1913, he was holding to his original belief, that in the deep-sea water was some element of life, which he called "marine plasma," for he had found the vital force in it was very unstable. He could neither boil the water nor keep it more than a few days without a total loss of its healing power. I suggested to him, at that time my belief that he was dealing with a weak emanation of radium, but we could not agree. Within a few months, however, Professor Jolie's paper appeared claiming his discovery of rich deposits of radium in the deep-sea dredgings, and his subsequent assertion of the radioactivity of the whole ocean body. Thus we had in the administration of freshly prepared solutions not only a natural food, but also the dynamic force of radioactivity to stimulate the activity of the cells and increase their power of absorption.

So much for the prologue, now for the story; what will it do?

In the first place I will state how it is prepared, and then as briefly as possible outline the conditions where it has proved of benefit.

The water is obtained out in the open ocean, in a region free from the contamination of sewage, and out of the track of vessels. I use a sterile glass bottle of a gallon capacity, and with a very small neck. This is dragged rapidly down to the depth of about 100 feet by a heavy weight attached to the rope and several feet below the bottle. It remains at that depth for fifteen minutes, and is then drawn to the surface and sealed. In my laboratory it is diluted with pure spring water in the proportion of three parts of the sea water to five of the other, and in order to make it permanently radioactive, 5 micrograms of a solution of radium barium bromide is added to every 1,000 c.c. of the mixed solution. It is then passed through a porcelain filter, and afterwards sterilized by heat. The dose varies from 10 c.c. to 200 c.c.

It can be injected with any large syringe which can be sterilized, but the best way I believe is by means of an apparatus which I have devised, patterned somewhat after that used in Paris. The accompanying illustration, I think, explains itself. It consists of (a) a glass reservoir to hold the solution, having corrugations in each of the extremities, so that the rubber tubes will not slip off; (b) a common atomizer bulb which goes on the curved extremity to pump up the necessary air pressure to expel the solution; (c) the rubber tube, which slips onto the straight end and carries the needle and the

brass attachment onto which the needle is screwed; (d) a small tunnel, of agate ware preferably, with a flexible rubber tube which slips onto the curved end and is used to pour the solution into the reservoir. The injection can be given in the back, sides of the abdomen, or, and this is the location of preference, in the hollow space on the thigh, just back of the greater trochanter. If the flesh is grasped tightly and held so while the 24-gauge steel needle is quickly thrust straight in, there is almost no pain. I use the same area from start to finish on a case. Of course it goes without saying that surgical asepsis should be maintained throughout.

Quinton claims, and my own experience verifies it, that the sea water is practically an absolute specific in the enteric diseases of infants. He sees the worst types of the disease brought in from the slums of the city, and by this treatment saves almost every one. I shall never forget the first case of a fatal type that I treated in this manner. A child 6 weeks of age, suffering from acute gastroenteritis, was apparently moribund at the time of my visit. I hardly expected to find it living when I got back from a hasty trip to my office to get the sea water; 200 c.c. was injected and before it was all in the child began to grow warm and show signs of life. The improvement was most marvelous, for an experience of over twenty years assured me that the case was hopeless. Since then I have learned always to expect a recovery in these conditions when treated in this manner.

As a general tonic after a severe sickness, I believe it is without a peer, while time and again I have been able to build up a surgical case that on account of general debility was apparently hopeless, so that in a very short time my patient was able to undergo a major operation successfully. Again I use it as a routine practice in the convalescence following all my severe surgical work, and am sure that I derive great benefit from it. In simple anemia and chlorosis, and as an adjunct to thorium X in the treatment of the pernicious type it is of proved worth.

In various skin affections, especially psoriasis and chronic eczema, Quinton has done some very remarkable work, and has a collection of photographs of cured cases that cannot be duplicated. My own experience in this line has been small, but my results have been equally striking.

In elderly patients the effect of the treatment is very gratifying; in fact, they seem to respond a good deal as do the children, and were it not for taking up too much space I could narrate some very interesting illustrative cases.

Another class of disease where I employ it as a most satisfactory routine treatment, is neurasthenia, and every medical man can test this very nicely in his own experience. There are always times in our busy life when the work comes so fast that we are tired out, and it is hard to keep going. This is the condition that has steered so many of our profession into the use of alcoholic stimulants and drugs. The effect of the solution in this condition is simply magical, as I can testify from many personal experiences. In my own case I pass, in about twelve hours, from a condition of exhaustion, to one of perfect well being, and this condition persists.

As for contraindications, I know of none. In the five years that I have employed it, and I use it very largely, I have never seen the slightest harm come from its use, barring a small number of ab-

scences in the early days, that were directly traced to a septic needle.

In conclusion, I believe that the medical world owes a debt of gratitude to Prof. René Quinton which as yet it but little realizes, but some day will to the uttermost, as the treatment becomes more generally known.

Medicolegal Notes.

Burden of Proof of Negligence Is on Plaintiff.—In an action for damages against a physician for the negligent performance of a surgical operation, in that a gauze sponge was negligently left in the plaintiff's abdomen, it was held to be injurious error to charge at the request of the defendant's counsel that, "If you find that the gauze was left in the abdomen of plaintiff and the incision sewed up by defendant or allowed to heal over it, the burden of proof is on defendant to show that it was not left there by any carelessness or negligence of his." In an action for negligence, the burden of proving the negligence of the defendant is upon the plaintiff, and as a proposition of law for the jury's guidance at the close of the case, it never shifts to the defendant.—*Niebel v. Winslow*, New Jersey Court of Errors and Appeal, 95 Atl., 995.

Excessive Damages for Personal Injuries.—In an action for personal injuries in which the plaintiff recovered a verdict of \$8,750, the liability of the defendant was admitted, but the case was appealed on the ground of excessive damages. In cutting the damages down to \$2,000 the court said: "A careful study of the evidence shows that the verdict was unconscionably excessive. This case presents a typical illustration of the extremes to which reputable physicians will sometimes go in testifying in behalf of a patient, and the boundless latitude over which pathology, diagnosis and prognosis will permit them to range. To give an intelligent analysis of the evidence in this case would require a space beyond the confines of any ordinary opinion, and serve no useful purpose. Seventeen questions were submitted to the jury which, with the subdivisions, required thirty answers. The questions were all couched in medical language, and many of them were of a highly technical nature.

"To illustrate: Question 9. Did plaintiff receive an injury to pelvic floor caused by defendant's negligence? Question 16. Is the plaintiff's condition caused by the defendant's negligence such that an operation, to wit, hysterectomy, will have to be performed? Question 17a. Is she suffering from general traumatic neurasthenia and inertia of nerves controlling the blood supply of the uterus? Twenty-seven of the answers were in the affirmative. To sixteen the jury, to their credit, said, "Do not know." These questions were all taken, seriatim, from the plaintiff's specifications of her injury; the only change being the interrogatory form.

"It is not difficult to perceive that the jury, with these specifications before them in their room, were overwhelmed with the array of medical inquiries and technical terms. If they were bewildered, it is without wonder; and that their verdict might be exaggerated, upon affirmatively answering this array of questions, all indicating different forms of disorder resulting from injury, might well be expected."—*Wingate v. Waterville F. & O. Ry. Co.*, Maine Supreme Court, 95 Atl., 882.

Degree of Care Required.—In an action for malpractice it appeared that an operation for pleurisy was performed on a child, and a tube placed in the incision to drain it and fastened by a safety pin to gauze wrapped around the tube. Through improper manipulation of the dressing by the child's mother the tube slipped inside the child's body and, when the defendant relieved another doctor in the treatment of the case, could not be found. The mother, though insisting that the tube might be in the child's body, denied that she had interfered with the dressing, and, in view of the impossibility of the tube entering the cavity unless the safety pin was removed, the defendant was misled into believing that the tube could not be in the cavity. It was held that, under such circumstances, the defendant exercised such care as ordinary medical skill and knowledge required by directing the mother to take the child to a hospital for an operation if she believed the tube was in the body.—*Cyr v. Landry*, Maine Supreme Court, 95 Atl., 883.

THE OSSEOUS DYSTROPHIES SIMULATING BONE TUMORS.

WHEN Virchow, in 1877, systematically opened all the long bones of an aged woman who had died from diffuse lymphosarcoma and found in the right humerus a cyst the size of a large walnut which he considered due to the breaking down of a cartilaginous metastasis, he promulgated the theory of neoplastic origin of simple bone cysts. His observation attracted slight notice at that time, and but little attention was paid to these lesions until the development of the x-ray led to their occasional recognition in the attempt to differentiate various bone lesions. When operative statistics as well as autopsy findings and studies of their histological structure began to appear in the literature, it was found that many of these bone cysts did not at all conform to the neoplastic idea advanced by Virchow. Abroad, the reports of von Recklinghausen, Rehn, Mikulicz, Mauclaire, and others; in America, the studies of Bloodgood, the late Carl Beck, Barrie, and others have brought this type of bone lesion adequately before the surgeon, from the standpoint of both the diagnostician and the pathologist; so that now the progressive surgeon and the expert radiologist are on the lookout for simple bone cysts, especially in cases of spontaneous fracture in early life, as well as for tumors of a malignant nature.

The most recent contribution to this subject is that of Bérard and Alamartine in the *Revue de Chirurgie* for August, 1914-November, 1915. They report three personal cases and a résumé from the literature of twenty-five others which they considered to conform to the type (fibrocystic osteodystrophy) which they discuss in their paper. By way of introduction they first remind the reader that there occur in certain of the long bones—sometimes in the epiphysis, sometimes in the diaphysis—localized dystrophic lesions entirely independent of any neoplastic process, which are capable of simulating, clinically, tumors of the bone, and that these lesions are well known to-day, thanks to radiography and to the sufficiently numerous surgical interventions to which they have given place. According to the anatomicopathological form which they take on, they have been variously called simple cysts of the bone, spongy callus, fibrocystic osteodystrophies, but the authors believe these form only a single group, "pseudotumors of bone by osteodystrophy."

In considering the etiology the authors point out that the age of the patients varies within narrow limits and that the malady is one of the period of growth. They find that but rarely does the age exceed 30, and that if, in these latter cases, one examines minutely into the previous history, one usually finds that the affection is of long standing and dates from adolescence; in this they agree with Mikulicz. In the anamnesis of these patients one does not generally bring out a history of any previous osseous affection such as rickets, osteomyelitis, tuberculosis, or syphilis. By far the most prominent among etiological factors is the history of traumatism. This would seem to be shown by the fact that of eighty-four observations of bone cysts collected by J. Mutel, in twenty-four there had been one or more previous fractures and in twenty-six there was a definite history of one or many previous contusions, and eliminating the cases in the literature where the history was lacking, Mutel found that of sixty-three cases forty-seven, or about 80 per cent., followed contusion or fracture. Bérard and Alamartine, however, hold that traumatism as a causal factor is not always demonstrated, and that often it merely brings about examination by the surgeon which then reveals the presence of an already existing lesion.

There are four principal theories as to the pathogenesis of these cysts, namely, the neoplastic, the infectious, the traumatic, and the trophic. The authors discard the first two of these as based on errors of diagnosis or misinterpretation of findings, while their convictions as to the insufficiency of the traumatic theory have already been alluded to. Of the trophic theory they say that the histological characteristics of the lesions found compel adherence to it. In support of this they call attention to numerous facts, one of which is that these cysts are found near the epiphysis or the center of the diaphysis, and they state in explanation that at the level of the epiphysis the arterioles have the character of terminal vessels and that the nourishment of the bone is equally precarious at the middle portion of the diaphysis, while they also consider that functional trouble in the glands of internal secretion which influence bone growth have to be taken into account, as seemed apparent in one of their personal cases.

As to treatment, we find that the most frequent intervention has been opening of the cyst and curetting its walls, packing, and wound healing by granulation. In some cases the periosteum and soft parts have been turned down and the cyst space obliterated by organization of blood clot or filled with Mosetig-Moorhof wax. These two types of operation apply more especially to the cases in which the cysts have been relatively small. For the more extensive cases with voluminous cysts, and for those with almost complete destruction of the continuity of the shaft, numerous operative procedures have been employed, including, in recent years, the transplantation of a portion of the clavicle (Delanglade), the fibula (Lexer), and the tibia, after resection of the diseased area. Since these lesions are non-malignant, the treatment should be as conservative as possible.

Upon the basis of their extensive study of the

question the authors feel that the following conclusions are justified: "There occur in certain long bones of the extremities, sometimes in the juxta-epiphyseal region, sometimes in middiaphysis, certain dystrophic lesions capable of simulating, clinically, tumors of the bone. These lesions are met with in the anatomical form of a fibrocystic osteitis of central origin; they may take on rather variable microscopic appearances (solitary cyst of the bone, spongy callus, fibrocystic pseudotumors). These lesions are neither inflammatory nor neoplastic. They result from a derangement in the nutrition of the bone. The cause of this derangement is rather difficult to determine. The influence of traumatism has often been imputed. Insufficiency of the glands of internal secretion which regulate the nutrition of osseous tissue, notably the thyroid, likewise seems an etiological factor. Taking advantage of the clinical history of the patient and the radiographic findings, it is possible if not to be certain of the diagnosis at least to suspect it and avoid confusion with an osseous tumor. The interest in this diagnosis is considerable, the prognosis and the therapeutics being essentially different in the two cases. These lesions, in fact, are of a benign nature and essentially curable. The intervention will consist in as conservative an operation as possible. . . . Recurrences never take place and the functional results are excellent, at least whenever the extent of the lesions has not rendered considerable osseous removal necessary, which is exceptional."

We have given a somewhat extended review of Bérard and Alamartine's article, since the subject should be of very considerable interest to the surgeon and is one that has received adequate attention by comparatively few in this country. We have presented a review uncolored by our own theories or opinions; but we shall be surprised if some of the views expressed by the authors go long unchallenged.

THE CAMPAIGN AGAINST TUBERCULOSIS.

THE fact has been insisted upon frequently that tuberculosis will not be abolished by relying upon sanatorium and hospital treatment alone. In order to have a fair chance of fighting tuberculosis with success the disease must be attacked in its stronghold, the home. The recognition of the house as the breeding ground of tuberculosis led to the creation of the Tuberculosis Dispensary, and the urgency of the question, according to Sir Robert W. Philip (*Medical Press*, February 16, 1916), has been emphasized by the facts which the dispensary has unearthed.

For example, it has been shown that in 60 to 70 per cent. of the tuberculosis cases under the care of the dispensary there existed all the possibility for infection; that is to say, persons living in a given household had been for prolonged periods in close proximity to one case at least of advanced tuberculosis. It has been similarly recorded how in more than 65 per cent. of the cases studied in one center the tuberculous patient occupied the same bed with one or several persons, and that in more than 75 per cent. of the cases the tuberculous patient occupied,

if not the same bed, at least the same room. Investigations in Edinburgh, and it may be said in all cities—New York, for instance—in which such have been undertaken, have revealed the hopeless ignorance which prevails among the masses regarding the treatment of the tuberculous patient and the need for avoiding infection. It has been proved that tuberculosis is essentially a house disease, and that in crowded centers numerous dwellings exist which may be best described as tuberculosis nests. They have pointed to the urgent need which exists for the hygienic education of the people at large by skilled and sympathetic teachers, and the training of fathers and mothers in the physiological principles which govern the rearing of healthy children.

The first step—or rather the most important step, for it has already been taken to some extent—is the provision of better houses. So long as people are massed together like sheep in unsanitary dwellings, just so long will tuberculosis flourish. But it is also necessary that knowledge be diffused as to the best use to be made of accommodation and resources actually at the disposal of the household. Knowledge with respect to tuberculosis in all its phases should be disseminated by word of mouth and by writings and posters throughout the length and breadth of the land. The New York City and State boards of health have set an example in this direction, and much good has been accomplished by the educational campaigns which have been initiated and carried on by their health officers.

SAWING OFF LIMBS.

JUDGING by most of the references to medical students and young doctors in fiction it might easily be supposed that these individuals spent the major portion of their waking hours amputating limbs. The medical student refers casually to the fact that he is just going to help saw off an arm and the genial family doctor remarks jovially that he must be excused, he is going out to cut off a leg or two.

In the present war there has been some tendency to revert to the methods of antiquity in amputations. It is much easier of course to perform a plain circular section than to do a more elaborate amputation and in field surgery where every moment must be utilized, anything which saves time is naturally considered. This method has been especially recommended for cases of gas gangrene, it being alleged that it leaves no recesses for the collection of poisonous matters. It has been therefore suggested that in many cases a plain circular section might profitably be made in the field and the case transferred to the hospital where later on another amputation could be done at one of the preferred sites.

Writing in the *Lancet* for October 9, G. A. Wright calls attention to some disadvantages of this method. In the first place it requires an inordinately long time for the stump to heal owing to the large area which has to be granulated over. The result too is not satisfactory, a large cicatrix being left with the bone pressing against it. The theory that the operation can be done as a temporary means to be succeeded later on by a more elaborate operation is all very well, says Wright, but in prac-

tice the patients often refuse a second operation. Having been subjected to one surgical procedure and passed through a long, tedious healing process, they are naturally averse to undergoing this ordeal again.

So it would seem that the disadvantages of this method outweigh the advantages and that it should not be used except in cases of great emergency. It would behoove then those physicians who are brushing up on their surgery, having caught the preparedness spirit, to devote part of their time to the latest and best methods of amputation.

LIFE-SAVING INTRACARDIAC INJECTIONS.

THE injection of cardiac stimulants directly into the heart muscle or ventricles of dying patients is doubtless an old procedure, but with little or no permanent benefit to report from it. Had results been attained which were commensurate with the kind and degree of the intervention, such resources as direct cardiac massage and simple needling of the heart would not be regarded as the very last resort in heart failure. Cases of life saving may have occurred in which intracardiac injection may have been one of a number of desperate remedies invoked.

Ruediger, in the *Muenchener medizinische Wochenschrift* for January 25, reports a case in which life was practically restored to an elderly woman by an intracardiac injection of a little strophanthin. The case occurred in the Marburg Medical Clinic. An elderly woman had been admitted in a state of cyanosis and edema of cardiac origin. There was double hydrothorax. The heart was dilated on both sides, pulse 140 and fluttering. The original lesion was apparently mitral, both obstruction and regurgitation. To the ordinary cardiac stimulants there was absolutely no response. The author tried to find a vein in which to inject strophanthin, but owing to the feebleness of the circulation none could be located. The injection was then thrown directly into the heart muscle and the response was prompt and decisive. The patient was now placed upon the indicated treatment and made a relative recovery. She remained in the clinic for five months and was in such a good condition when discharged that she may survive under favorable conditions for a number of years.

Animal experiments have shown that in intracardiac injections there is no danger of air embolism, because even if air enters the ventricles no harmful results can be noted. Again, the puncture made by the needle closes up so promptly that in a day or two no trace of it can be found. The author has performed the operation a number of times since 1909 and has evolved a technique. The injection should be aimed at the base of the heart, where motion is least. The upper part of the right ventricle seems to be the best site.

SUGAR AS A WOUND DRESSING.

WHILE glucose is used extensively by the mouth in hyperchlorhydria and gastric ulcer and is employed to some extent by the rectum after surgical operations, with the view of diminishing shock and pre-

venting acidosis the topical application of cane sugar to wounds appears to result in nothing more than absorption of secretion in cases not yet infected. It would hardly be supposed to be of any more use than any ordinary dusting powder. Nevertheless there are special traumatic conditions in which sugar may give superior service. Thus Dr. Erich Meyer contributes a short article to the military supplement of the *Münchener medizinische Wochenschrift* for January 11, in which he relates his experiences as surgeon to a mining company. The miners frequently injure themselves and in practically all cases the wounds are contaminated with coal dust. In theory such lesions should be carefully cleansed. As ordinary granulated sugar is available in large quantities the author began to dress these dirty wounds with it, after merely flushing with hydrant water, using no other dressing except a simple compress. The sugar was renewed every second or third day, and in 70 per cent of these injuries no infection followed, while healing was unusually prompt and sound. The use of sugar completely prevented adhesion to the dressings and the resulting hemorrhage.

SURGICAL TREATMENT OF LUPUS VULGARIS.

THE most effectual remedy for lupus thus far discovered is the Finsen light treatment, which requires weeks and months of time. In military surgery this delay is quite impracticable. Soldiers who are admitted to the ranks with lupus usually have their malady much aggravated by warfare; and in such cases excision and plastic surgery become the indication of necessity. At the Royal Imperial Medical Society of Vienna last January (*Muenchener medizinische Wochenschrift*, February 15) Spitzer, of the Vienna Lupus Institute, reported the cases of 40 soldiers with lupus of the skin of years' duration treated with excision and plastic repair. The total number of such cases treated by this means at the institute now amounts to 650. The average duration in hospital is from two to three weeks for the simpler cases. In those who have been neglected, so that mutilating effects have been brought about, additional prosthesis is required, especially for the nose, ear, etc. Operation is done under local anesthesia. In diffuse lupus surgery is, of course, contraindicated.

News of the Week.

New York City Death Rate.—The death rate for the first sixteen weeks of the present year is given by the Department of Health as 15.57 per 1,000 of population, the lowest on record for the period; last year for the same time, the rate was 15.59. During the week ending April 15, the rate was 14.52 per 1,000, representing a total of 1,555 deaths, as compared with a rate of 17.01 and a total of 1,778 for the corresponding week of 1916. The reduction occurred chiefly in the mortality due to influenza, lobar and bronchopneumonia, and heart diseases; the mortality from measles, diphtheria, tuberculosis, and Bright's disease was somewhat higher than in the corresponding week of last year.

Deaths in Chicago.—During the week ending April 15, there were reported in Chicago a total of 767 deaths, giving a death rate of 16.1 per 1,000, the same as for the corresponding week of 1915, but an increase as compared with the previous week of this year, when the rate was only 13.9 per 1,000.

Fellowship Award.—The Mary Putnam Jacobi Memorial Fellowship, which was recently announced in these columns, has been awarded to Dr. Mildred Clark, a graduate of the Johns Hopkins Medical School in 1914. Dr. Clark will carry on researches in medical bacteriology under Prof. Theodore C. Janeway in the department of medicine at the Johns Hopkins Hospital.

Recruits for the Medical Brotherhood.—Dr. William J. Gies, first secretary of the Medical Brotherhood, has received a letter from the secretary of the Nederlandsche Vereeniging voor Heelkunde, informing him that this society had decided to enroll as a member of the Medical Brotherhood. In addition twenty-four well-known surgeons of Holland have already enrolled individually as members of the Brotherhood.

Personals.—Dr. William H. Dukeman of Los Angeles, Cal., for many years an occasional contributor to the MEDICAL RECORD, retired from active practice at the first of the year.

Dr. Elizabeth M. Baer of Philadelphia is a candidate for election as representative-at-large to Congress on the Socialist ticket.

Dr. William H. Steers of Brooklyn, N. Y., has been appointed major in the medical corps of the National Guard of the State of New York.

Centenarians in New Jersey.—Miss Celeste Yeandle of Hoboken, N. J., said to have been the oldest woman in the State of New Jersey, died at her home recently in her one hundred and second year, while Mrs. Margaret McCandless of Elizabeth, N. J., died on April 18, having just completed her one hundred and first year. Mrs. McCandless left four sons, twenty-one grandchildren, and five great-grandchildren.

Medals and Medicine.—The Army Medical Museum at Washington already houses a valuable collection, made by the late Dr. John S. Billings, of medals relating to medicine, and it is now desired that this collection should as far as possible be completed. The librarian of the Surgeon General's Office, therefore, requests the advice and assistance of physicians who are collectors of medical medals. The museum appropriations are sufficient to permit the purchase of individual medals not in the collection, the purchase of private collections will be considered, private donations of medals or groups of medals will be most welcome and will be duly credited to the donors, and the transmission of catalogues of medals for sale is requested. Communications on the subject may be addressed to Lieut.-Col. C. C. McCulloch, librarian, Surgeon General's Office, U. S. A.

Tuberculosis Sanatorium for South.—The gift of 700 acres of land near Asheville, N. C., for a tuberculosis sanatorium was announced by officials of the Southern Sociological Congress in session at New Orleans on April 14. The donor is Mrs. D. B. Safford of Hot Springs, N. C., who has also given \$20,000 as a nucleus for the building fund of the sanatorium.

New Home for Blind.—The Society for the Relief of the Destitute Blind, New York, having outgrown its present quarters at Amsterdam Avenue and 104th Street, will erect a new building at Grand Boulevard and 193rd Street. The new home, which, with the site, will cost about \$400,000, will be a three-story fireproof structure, so planned that a fourth story may be added when greater accommodations are needed. It will be colonial in design, with walls of rough red brick with white trimmings,

and will be built in two wings forming an L, the inclosed space being used for a garden. It is expected that the building will be ready for occupancy next November.

Reportable Diseases.—The Public Health Council of the New York State Department of Health, at a meeting on April 4, passed the following resolution: "It is the judgment of the council that laboratory facilities in the State, both within and without the department, being now adequate to make diagnostic examinations in diphtheria, typhoid fever, and tuberculosis, it is feasible and desirable for the department to enforce the sections of the sanitary code relating to prompt and uniform notification in these diseases by such means as will compel physicians at once to seek laboratory assistance in diagnosis in all doubtful cases."

Measles at Princeton.—Because of an outbreak of measles among the student body of Princeton University, the Easter holidays have been extended until May 1. About 300 cases of the disease have occurred in the town since the first of the year, and eight students are now in the infirmary.

Sick Poor Hospital.—The Nursing Sisters of the Sick Poor of New York City are collecting funds with which to erect a hospital for the free treatment of the poor of all classes. For thirty-eight years the Sisters have carried on work among the sick poor in their own homes.

To Study Health Insurance.—The New York State Legislature on April 17 passed the Mills bill, creating a commission to investigate the question of health insurance for workingmen and to recommend legislation on the subject to the Legislature of 1917. The bill carries an appropriation of \$25,000 for the work, and provides that the commission shall consist of two senators, two assemblymen, and five other members to be chosen by the chairman.

New Hospital to Open.—The new Huntington (Long Island) Hospital will be opened for patients on the first of May. The building, which cost \$100,000, is a gift to the town from Miss Cornelia Prime.

Gifts to Charities.—Mr. Henry W. Putnam of New York has given the sum of \$90,000 to the building fund of the proposed new hospital at Bennington, Vt., as a memorial to his father.

The Albany Hospital, Albany, N. Y., receives a bequest of \$5,000 under the will of the late Mr. H. T. Martin of New York for the endowment of a bed in memory of the testator's brother, Frederick Townsend Martin.

By the will of the late Jacob Frankenthal of New York, Mount Sinai Hospital, the Montefiore Home, and the Home for Aged and Infirm Hebrews receive bequests of \$1,000 each.

By the will of the late Fanny Brown of Philadelphia the sum of \$10,000 is bequeathed to the Presbyterian Hospital.

By the will of the late Sarah D. Cox of Philadelphia the sum of \$5,000 is bequeathed to the Hahnemann Hospital and a portion of the residuary estate to the Germantown Hospital.

By the will of the late Samuel Hazard of Philadelphia, who died recently at Los Angeles, the sum of \$1,000 is bequeathed to the Germantown Hospital.

By the will of the late Maria S. Wilson of Philadelphia the sum of \$5,000 is bequeathed to the Episcopal Hospital of that city, to be added to the endowment fund.

Rice Memorial Hospital.—Because of the protests of the inhabitants of Irvington, N. Y., the plan

to establish in that town the convalescent home to be built as a memorial to the late Isaac M. Rice has been abandoned, and announcement is made of the choosing of a new site at North Tarrytown. An estate, comprising twenty-four acres, on New Broadway, has been purchased, and it is hoped that work on the buildings can soon be begun. The site, it is said, has cost \$70,000, and an additional \$200,000 will be expended for construction.

Medical Society Elections.—TENNESSEE STATE MEDICAL ASSOCIATION: The annual meeting was held in Knoxville during the first week of April, when the following officers were elected: *President*, Dr. C. F. Crowder, Nashville; *Vice-Presidents*, Dr. C. J. Carmichael, Knoxville; Dr. J. T. Moore, Algood, and Dr. John L. McGehee, Memphis; *Secretary*, Dr. Olin West, Nashville. The next meeting will be held in Nashville.

NEW LONDON COUNTY (CONN.) MEDICAL SOCIETY: At the one hundred and twenty-fifth annual meeting of this society the following officers were elected: *President*, Dr. George Thompson, Taftville; *Vice-President*, Dr. William M. Hill, Noank; *Secretary-Treasurer*, Dr. L. F. La Pierre, Norwich.

FAIRFIELD COUNTY (CONN.) MEDICAL SOCIETY: At the annual meeting in Bridgeport on April 11, the following officers were elected: *President*, Dr. Frank H. Barnes, Stamford; *Vice-President*, Dr. F. M. Tukey, Bridgeport; *Secretary*, Dr. Eli B. Ives, Bridgeport; *Treasurer*, Dr. H. B. Lambert, Bridgeport.

Tuberculosis Day Camp.—The report of the New York City Day Camp "Rutherford" for 1915, just issued by the Department of Health, states that during the year 274 patients were cared for, of whom 138 were adults and 136 children. Of the patients who remained for a month or more, 126 were discharged during the year, 3 because they were found to be non-tuberculous, while 5 were transferred to the Night Camp. Of the remainder, on admission 63 were classed as incipient, 48 as advanced, and 7 as far advanced, while in discharge 33 were apparently arrested, 33 were quiescent, 31 improved, and 21 unimproved. Over 75 per cent. of the pupils have been found to continue in good health, due largely to the "follow-up" work of the nurses attached to the camp. The Night Camp is conducted along the same general lines as the Day Camp, and is designed to care for patients who are able and obliged to work during the day and are in need of the opportunity afforded by the camp. At present it has accommodations for twelve male patients.

Medical Society of the Missouri Valley.—The spring meeting of the society was held in St. Joseph on March 23 and 24, under the presidency of Dr. John P. Lord, Omaha. Dr. Charles A. L. Reed, Cincinnati, made an address on recent developments in idiopathic epilepsy, claiming that the germ producing epilepsy had been discovered, and Dr. Mazyck P. Ravenel of the Missouri State University spoke on sera and vaccines. A number of other interesting papers were presented.

American Climatological and Clinical Association.—The thirty-third annual meeting of this association will be held in Washington on May 9, 10, and 11, in connection with the tenth congress of American Physicians and Surgeons. The scientific meetings will be held at the New Willard Hotel, under the presidency of Dr. James Alexander Miller of New York, and the annual dinner will be given at Rauscher's on the evening of May 10. Details

of the program can be obtained from the secretary of the association, Dr. Guy Hinsdale, Hot Springs, Va.

American Gastro-Enterological Association.—The nineteenth annual meeting will be held in Washington on May 8 and 9, at the New Willard Hotel, under the presidency of Dr. Charles G. Stockard of Buffalo, N. Y. Dr. Franklin W. White, 322 Marlboro Street, Boston, is the secretary of the society.

Harvey Society Lecture.—The eleventh lecture of this course will be delivered at the New York Academy of Medicine on Saturday, April 29, at 8.30 P. M. by Dr. William H. Welsh; subject, "Medical Education in the United States."

Hospitals Chartered.—The State Board of Charities on April 12 approved the charter for the new Broad Street Hospital, New York, calling for a general emergency hospital and a nurses' training school, thus assuring the completion of the project of a hospital to serve the million and a half of people who are employed in lower Manhattan during the day. The granting of the charter was protested by Bellevue Hospital, the New York Hospital, the Volunteer Hospital and the Ambulance Board, on the ground that the existing institutions were sufficient to cover the territory; their protests were, however, overruled. Dr. A. J. Barker Savage will be the superintendent of the new hospital.

The State Board at the same time approved the incorporation of the Canandaigua Hospital, Canandaigua, and of the Bush Terminal Hospital, Brooklyn.

Colleges Cooperate.—Columbia University, New York, and the Long Island College Hospital, Brooklyn, which have already entered into an agreement by which the university offers certain courses at the college, so that the graduates of the latter receive the degree of bachelor of arts or bachelor of sciences as well as that of doctor of medicine, have extended their cooperation so that the university will in future give graduate courses in history and sociology in the medical college buildings. The medical school will lend the lecture rooms for the purpose, and the courses will be given by Columbia professors. It is hoped that the plan may soon be extended so as to include graduate courses in politics and English as well.

Mosquito Week.—The plans for the proper observance of mosquito week in New York are being pushed. The town of Forest Hills on Long Island has already raised a thousand dollars for the campaign, and Commissioner of Health Emerson has announced that the Gutman swamp, the chief breeding place for mosquitos in the neighborhood of Forest Hills and Jamaica, is to be drained by the construction of a temporary sewer. As the expense of mosquito extermination is slight in comparison to the results returned, the slogan of the campaign is to be: A dollar kills a million.

Obituary Notes.—Dr. ROBERT M. CURTS of Paterson, N. J., a graduate of Trinity Medical College, Toronto, Ontario, in 1892, and a member of the American Medical Association, the Medical Society of New Jersey, and the Passaic County Medical Society, died at his home, on April 16, aged 50 years.

Dr. ANDREW J. RICHARDSON of New York, a graduate of the New York Homeopathic Medical College and Hospital in 1870, attending physician at the Yorkville Homeopathic Dispensary and at the New York Christian Home for Intemperate Men, con-

sulting physician at the Baptist Home for the Aged, and a member of the American Institute of Homeopathy and the State Homeopathic Medical Society, died at his home, on April 17.

Dr. ORIN WARREN of West Newbury, Mass., a graduate of the Jefferson Medical College, Philadelphia, in 1858, died at his home after a short illness, on April 4, aged 83 years.

Dr. EMIL V. KLINKOWSTROEM of Denver, Col., a graduate of Rush Medical College, Chicago, in 1896, died suddenly at his home, on April 2, aged 62 years.

Dr. THOMAS W. DORSETT of Willacoochee, Ga., a graduate of the Atlanta College of Physicians and Surgeons in 1902, died at his home, on April 5, aged 37 years.

Dr. ALBERT L. MARDEN of Claremont, N. H., a graduate of the Dartmouth Medical School, Hanover, in 1874, died at his home, after a short illness, on April 2, aged 67 years.

Dr. HUGH SCHUSSLER, formerly of Chicago, a graduate of the Hering Medical College, Chicago, in 1897, and of the Northwestern University Medical School in 1903, died at his home in New York, on April 16, aged 40 years.

Obituary.

JAMES WILLIAM WHITE, M.D., LL.D.

PHILADELPHIA.

DR. JAMES WILLIAM WHITE, emeritus professor of surgery in the University of Pennsylvania, Philadelphia, and a trustee of the university, died at his home, after a long illness, on April 24. Dr. White was born in Philadelphia on November 2, 1850, and was educated in the Philadelphia public schools and at the University of Pennsylvania, from which he received the degree of doctor of medicine in 1871. Immediately after graduation he joined the staff of Prof. Louis Agassiz and accompanied him on the Hassler expedition to the West Indies, the east and west coasts of South America, and the Galapagos Islands. Returning to Philadelphia the following year he began the practice of surgery, and entered the department of surgery at the University in 1881 as a demonstrator. He was appointed successively professor of genitourinary surgery, professor of clinical surgery, and John Rhea Barton professor of surgery, the last appointment dating from 1900. During this time he served as attending and consulting surgeon at several of the Philadelphia hospitals, and was also interested in many civic enterprises. Dr. White was a member of the American Medical Association, the Medical Society of the State of Pennsylvania, the Philadelphia County Medical Society, the American Surgical Association, the Philadelphia Academy of Surgery, the Pathological Society of Philadelphia, the College of Physicians of Philadelphia, the American College of Surgeons, and the Association of Genitourinary Surgeons, and was the author of a number of books and articles on surgical topics.

RICHARD STEIN, M.D.

NEW YORK.

DR. RICHARD STEIN died suddenly of apoplexy on Tuesday evening of this week while reading a paper before the Metropolitan Medical Society in one of the halls of the Academy of Medicine. He was born

in Bohemia in 1861, and after being graduated in arts from the College of the City of New York went to Berlin to study medicine, obtaining his degree there in 1884. He was a member of the New York County and State Medical Societies, the American Medical Association, the New York Academy of Medicine, the Metropolitan Medical Society, and the New York Pathological Society. He was visiting physician to the German and Lebanon Hospitals. He was a successful general practitioner and an earnest student of medicine, and was a frequent contributor to medical literature. The paper which he was reading when taken by death will shortly be published in this journal.

Correspondence.

THE USE OF SODIUM CITRATE FOR BLOOD TRANSFUSION.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—Referring to Dr. Rueck's article in the MEDICAL RECORD of April 15, it is evidently impossible to convince him that questions of priority are determined by the date of publication (see MEDICAL RECORD, 1915, 87, 448).

However, even if Dr. Rueck's communication had appeared before and not one month after my preliminary report, my method would still be the first one which made the citrate method a safe and generally applicable procedure, for my method is the only one which can be used in small and large transfusions with perfect safety and satisfaction (see *Surgery, Gynecology & Obstetrics*, July, 1915, and *American Journal of the Medical Sciences*, December, 1915).

RICHARD LEWISOHN, M.D.

105 FIFTH AVENUE, NEW YORK.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

EFFECTS OF TEMPESTUOUS WEATHER—SIR A. KEOGH ON MEDICAL ARRANGEMENTS FOR THE ARMY—ADEQUATE PREPARATION—THE LONDON HOSPITAL—NURSES' HOME.

LONDON, March 31, 1916.

MEDICAL questions, like all others, have been little spoken of all through the week, the tempestuous weather preoccupying our attention. The month as a whole has been the worst March on record. Snow has fallen in some parts of the country on 22 days out of 30, accompanied on many by high winds leaving deep drifts. A number of deaths are reported more or less directly due to the storms, as e.g. several persons have been killed by falling trees striking them, others by the overturning of their vehicles, others again have become entangled in fallen wires. The railway traffic has been greatly disordered, and on the long journeys the delays have lasted for hours—two, three, four; some even eight. The mail to Dublin on Wednesday was 20 hours late, rail and seas together, a most unpleasant experience for passengers. From London to the North of England one or two trains got through, and in some parts hand-signalling was called upon to assist and safeguard. At Portsmouth a football club's headquarters was carried away; at Sandwich an iron coop weighing two tons was blown 200 yards from its position. In the London parks the gales have played havoc with the trees, not a few branches being wrenched off some and others being uprooted. We were kept many

hours in anxious expectation owing to the interruption of communication by road, rail, telegraph, and even telephone. The casualties are of the most varied character ever reported—ships in distress, street traffic suspended, houses and buildings unroofed, trains delayed for many hours (five to ten in some cases). In some localities the wind attained a velocity of 70 to 80 miles per hour in the fierce squalls—enough to impede the most powerful express engines. In London the squalls exceeded 60 miles an hour. Hundreds of trees have collapsed in the parks and public gardens, about 20 are prone between two gates in Hyde Park, and there are more in the neighborhood of the Round Pond. Trains to northern towns have been held up in a number of places through signal posts and telegraph poles being blown across the lines, and the delay at several stations was increased by a shortage of workmen. A party of about 50 Manchester people who set out for London on Tuesday returned the next day without having arrived here. They were stranded on the way, and procured food at farm houses near the line. Snowdrifts cut all communication, covering roads and rails—in some cases to a depth of eight or ten feet. A rise of two inches in the Thames and its tributaries has given an expansive sheet of water over six miles or more. In more exposed parts of the Surrey hills the drifts were reported to be seven feet deep.

Sir Alfred Keogh is in charge of the medical arrangements of the army here, in France, and the Mediterranean. Speaking in London on Wednesday evening, he said that at last they might look the public fairly in the face and say they were doing their best. During the last ten years, he went on to assert, the Government had made adequate preparation for war on the medical side, and that was why when the present campaign began they were in a fit shape to take on the responsibilities that fell upon them. It was only right and fair for him to say, he added, that the minister responsible for this adequate preparation was Lord Haldane. They had been told what they must prepare for, so as to be efficient for it—that was, a great European war. He did not think the public had fully recognized this, and he would impress it on them now.

At the meeting of the governors of the London Hospital the report of the committee states that during the past year the in-patients numbered 18,933, an increase of 600; the out-patients were 149,507, about 20,000 fewer. A satisfactory fact was that in over 19,000 cases anesthetics were given, with only two deaths. The hospital had supplied 120 nurses to the army during the war, 26 to the navy, and they had been able to provide every nurse asked for; ten of them had been mentioned in dispatches in the last quarter, and three were killed in the accident to *H.M.S. Natal*. For the new nurses' home, which Queen Alexandra wished named after Edith Cavell, £10,000 has been raised. The increased cost of provisions has added greatly to the expenditure of the hospital.

Treatment of Psoriasis with Horse Serum.—Perry has reported success with the subcutaneous injection of horse serum for this disease, stating that, among others, a case of six years' standing has been apparently cured by six subcutaneous injections at weekly intervals, the eruption having entirely disappeared. He suggests that this remedy should be extensively tried out, care being taken with regard to anaphylaxis.—*Boston Medical and Surgical Journal*.

2. **What Shall Be the Attitude of the Public Toward the Recovered Insane Patient?**—H. C. Solomon points out that the misconception of the meaning of insanity and the prejudice of the ages is responsible for the reaction of the public toward the recovered insane patient. He thinks that if we could disabuse the minds of many of the impression that insanity means a wild maniacal state, if we can make them understand that the majority of the insane are quiet and apathetic, that many of the so-called cases of nervous prostration "nervous break-down," etc., are in reality cases of manic depressive insanity, and that many of these patients recover to such a degree that they show no symptoms and retain their former characteristics and abilities, we shall have done a great deal toward the solution of the problem that confronts the patient recovered from mental disease. The difficulties which confront the discharged patient because of the attitude of suspicion, fear, and avoidance are productive of just those conditions which favor a recurrence of insanity, since it is important that the recovered patient be kept busy and occupied and should be free from worry. The attitude that is desired is that of fair play. When it comes to the question of employing the person who has recovered from an attack of insanity, the public should seek information from the experts as occasion requires rather than avoid the problems by drawing back. This attitude of dependence upon those of experience would lead to the avoidance of mistakes in other directions, as for instance, marriage with a recovered victim of insanity. It would also avoid the overlooking of symptoms of importance, whereby the patient suffers from the charitable interpretation of his associates.

5. **The Roentgenoscopic Examination of the Stomach and Duodenum.**—George W. Holmes describes a method of making roentgenoscopic examinations of the stomach and duodenum which is much less expensive than the methods usually employed and by which the results obtained were at least as good as those obtained by the more expensive methods. During the year 1914, 730 roentgen examinations of the gastrointestinal tract were made. Of these 209 showed evidence of organic disease of the stomach or duodenum; 144 were operated upon and the findings proven or corrected. The writer analyzes this series of cases in detail and concludes that this method, which is a modification of that of Barclay and Carman, offers the best chance of obtaining correct roentgen findings with the least possible cost, and in hospital clinics is the method of choice. The technique is as follows: The patient is allowed a glass of milk or a cup of coffee and a piece of toast at 7 A.M. At 10 A.M., after taking a brief history of the patient in order to enable the examiner to conduct the examination in such a way that the greatest attention will be directed to the symptoms of which the patient complains, an opaque meal, consisting of 75 gm. of barium sulphate and 8 oz. of potato starch gruel, is administered through a drinking tube, while the patient stands behind the fluoroscopic screen, and its passage through the esophagus and entrance into the stomach is noted. The first swallow is taken with the patient in

the oblique position, after which the antero-posterior position is assumed, and the examination continued. In this way the entire course of the esophagus is observed, the position of the stomach, and at times irregularity on the greater curvature. Pressure on the normal stomach will often force the barium through the pylorus and show an outline of the sphincter and cap. In many cases the examination may be concluded at this time, but should any of the findings vary from the normal, the examination is continued with the patient in the prone position. The writer has found that by placing the patient face downward, or a little upon the right side, upon the table (the tube under and small screen over the back) it is possible to demonstrate the duodenum and pyloric sphincter in the great majority of cases. Any defect in outline which can be reproduced on the radiographic plate can be seen upon the screen in some of the various positions and phases. The patient is next given a small carbohydrate meal and told to abstain from food and drink for six hours, at which time he reports for a second examination. This meal is essentially a test meal and should be constant in size and character. The absence or presence of barium in the stomach is noted, also the ileum, cecum, and that part of the colon which is filled, are observed and palpated for fixed or tender points. A third observation is made at 10 A.M. the following day, at which time the position, outline, and contents of the remainder of the colon are studied.

6. The Incidence of Visceroptosis.—I. H. Levy and J. L. Kantor present a study based on a series of 1600 consecutive private patients complaining of "stomach trouble." Of this total, 898 were subjected to a routine x-ray examination. Marked gastroptosis occurred in 46.4 per cent., and some degree of gastroptosis in 64.4 per cent. of these cases. The condition was only slightly more frequent in women than in men, the proportion being about six to five. The condition occurred more often in individuals under forty than in those over forty years of age, and this relationship held for both sexes. Gastroptosis was more frequent in single than in married women, in the proportion of 13 to 12. In this series practically all single women over forty were ptotic. In addition to gastroptosis many of these cases had ptosis of other organs as follows: Liver 77 per cent., right kidney 30 per cent., heart 22 per cent., both kidneys 3 per cent., spleen 1 to 2 per cent. The above clinical study does not support the view that visceroptosis can be ascribed to improper garments, the occurrence of pregnancy, or to any other incidental cause. It seems that the condition is intimately related to the structure of the body, and probably arises from some congenital predisposition. Ptosis is not in itself a disease. While in some of its milder forms it may cause suffering and discomfort leading to a state of chronic invalidism; on the other hand, the most marked types need not necessarily prevent the affected organs from performing their proper functions.

1. Public-Health Laboratories.—Roger G. Perkins, in discussing the proper functions of the laboratory in the community, shows that in addition to its main duty,

namely, the prevention of epidemics by acquiring and giving out information to aid in the control of disease already present, it has become customary not only to aid in the diagnosis of diseases but to offer means of curing and means of prophylaxis, and also to assume other functions as well, such as those relating to the adulteration of foods and beverages. In certain other activities the laboratory acts as a consultant. Examination of the air in public places and in common carriers, testing of disinfectants, school cultures for diphtheria carriers, and similar matters are examples of this sort. In order that the public may reap the full benefit from the public health laboratory there are certain principles that it is well to observe. First, in routine work outside of the diagnosis division, especially where there are places or outfits to be inspected, samples to be collected and examined, and a possible termination in a court procedure, the closer the collector of the samples to the analyzer, the better the results. Secondly, where the laboratory work of the individual worker is highly specialized there is a tendency for the individual to become a cog in the mechanism and to lose touch of the relations of the work, as, for instance, the man who diagnoses positive or negative in diphtheria slides without knowledge of the clinical relations. For these reasons the diagnostician should know whether the physician considers the case diphtheria or not, whether the culture is for diagnosis or release, and in the latter contingency, whether the presence of the organism is of long or short duration. There should be a certain amount of field work for each man so that the clinical side may not fade, and that where it is considered wise to isolate cultures and to test them on animals this should be done by the man who has followed them through the microscope. This same rule holds good in other divisions of the work. By this method the ultimate results to the community are better in that it gives the worker a square deal, puts him in a position for advancement, and does not lower him to the rôle of a mechanic who is fit for but one job. Moreover this arrangement in the various divisions seems to stimulate the whole group to better and more conscientious efforts. A third point upon which the writer expresses his convictions is with reference to the question of research work in public health laboratories. He believes that there are many problems requiring research work which can only be properly handled in a public health laboratory and that the difficulties of conducting such work may be solved by establishing a close relation between the laboratory and an up-to-date university, since there are always men connected with universities who are interested and have the time for research work.

3. Blood Letting in Uremia.—Beverley Robinson relates the case of a patient with chronic interstitial nephritis who was in coma and convulsions when he was called in consultation. He applied one dozen leeches to the mastoids with very satisfactory results. He feels confident that the use of leeches would save not a few lives and avoid many operations. In uremia, cerebral hemorrhage, and pneumonia they would often be invaluable. In acute aural and ocular inflammations many operations would be prevented; likewise in attacks of appendicitis. The local effect of leeching is preferable to venesection in all these conditions excepting pneumonia. The author says he has seen more than one instance, even when venesection was carefully done, in which the vein did not give out blood as it should. He deplores the fact that it is so difficult to get leeches in the drug stores of New York City, there being, so far as he knows, but one store north of Fourteenth Street in which they can be obtained.

4. **Tuberculin in Surgical Tuberculosis.**—Ellis Bonime outlines his method of tuberculin treatment in surgical tuberculosis. He points out that in applying tuberculin treatment we must aim toward two distinct effects: First, the elimination of the hypersensitiveness to the products of the tubercle bacillus; second, the production of the maximum amount of antibody substances in order to eliminate the tubercle bacilli faster than they can increase. The former can be attained by using minimized doses of tuberculin gradually increased, while the latter may be accomplished by giving the maximum amount of tuberculin consistent with the individual's hypersensitiveness. The writer's method is as follows: Treatment is begun by giving 0.10 c.c. of a certain dilution of the tuberculin. This dose is increased by 0.02 c.c. for each of the two following injections, giving 0.12 c.c. and 0.14 c.c. respectively. Subsequently the increase is made by 0.04 c.c., then by 0.06 c.c., thus increasing the amount of increase by 0.02 c.c. at every second injection until 1 c.c. of that dilution is reached, when the next dilution is begun and given in the same routine as the former. This method allows of the maximum of tuberculin being given compatible with the tolerance of each individual case, and if a reaction is reached, it will not be severe, as it is produced by the minimum of tuberculin necessary in that particular case. The dilutions are made in multiples of 10, and this is done in a Record tuberculin syringe, subdivided into 0.02 of a c.c. The diluent is half of 1 per cent. carbolic in normal saline. The first 0.90 c.c. of diluent is drawn in, followed by 0.10 c.c. tuberculin. An air bubble is then drawn in, the syringe is shaken and the contents are put in a receptacle, and labeled Solution No. 1. Then 0.90 c.c. of diluent is drawn into the syringe with 0.10 c.c. of Solution No. 1; this is well shaken and labeled Solution No. 2; 0.90 c.c. of diluent and 0.10 c.c. No. 2 is solution No. 3, and 0.90 c.c. of diluent and 0.10 c.c. of solution No. 3 is No. 4. In most surgical cases treatment is begun with the fourth dilution, except in acute joint tuberculosis where the fifth dilution should be chosen. In the treatment of surgical tuberculosis the use of tuberculin does not obviate the necessity for the application of the usual surgical and orthopedic measures.

6. **Malnutrition.**—Ira S. Wile calls attention to the inadequacy of our knowledge regarding malnutrition among school children, and says that the extent to which malnutrition is productive of physical defects, or the degree to which physical defects are responsible for malnutrition, has not been determined. There interdependence seems to be certain. The solution of the problem of malnutrition is not at hand nor will be until medical inspectors give greater consideration to malnutrition. Considered as a unit defect, it possesses unusual significance in a constructive program for the establishment of the preventive and correctional measures necessary for the protection or the conservation of our school children. The mere placing of the word nutrition upon our blanks is insufficient. The concept should be positive and the defect to be recorded should be malnutrition.

1. **The Bacteriology and Experimental Production of Ovaritis.**—Edward C. Rosenow and Carl Henry Davis have made cultures in sixty-four cases of ovaritis, the patients ranging from 18 to 55 years of age, 26 being under 30 years of age. In fifty-six the records of the associated abdominal findings were quite complete; fibroids of the uterus were found in eighteen instances, salpingitis in eleven, chronic appendicitis in eleven, and chronic cholecystitis in eight. The technique of making the cultures was that used by the writers in connection with a study in other diseases. Two of the patients with tubo-ovarian abscesses showed pure cultures of *Streptococcus viridans* in countless numbers in the involved tissues. The pus of one of these was sterile, while the other showed a moderate number of the same streptococcus. The third acute case yielded the gonococcus in large numbers. In ten cases the cultures remained permanently sterile. In the remaining fifty-one cases in which the ovaries showed the usual fibrocystic degeneration, streptococci were isolated in twenty-nine, the number of colonies ranging from one or a few to countless numbers. They were present in pure culture in seven, and associated in the others with the Welch bacillus and a few staphylococci or colon bacilli. Welch bacilli were found in small numbers in twenty-one, diphtheroid bacilli in ten, a few colonies of *Staphylococcus albus* in nine, the gonococcus in two, the colon bacillus in three, and an aerobic streptothrix in one. In many instances cultures were made from both the cystic fluid and the tissue. The writers find that the following facts support the view that the streptococci isolated by them from the chronic lesions, when there was no history of a previous acute infection, as well as those causing acute infections of the ovary, are carried to these structures by the blood more often than is generally believed: 1. The occurrence of fibrocystic degeneration of the ovaries in which the usual streptococcus was isolated in pure form in a young woman with imperforate vagina. 2. The history of tonsillitis followed by symptoms of pelvic infection in a number of patients in this series. 3. The not uncommon occurrence of pelvic infection noted in gynecological practice following anginal attacks during the menstrual period. 4. The far more frequent occurrence of the idiopathic streptococcal peritonitis following anginal attacks in the female than the male, which, according to Wilder, is due to the occurrence of a primary hematogenous ovaritis and a secondary peritonitis. 5. The absence of colon bacilli in all but three ovaries in this series, a fact contrary to expectations if local invasion occurred commonly. 6. The frequent occurrence of appendicitis, cholecystitis, and arthritis in these patients, diseases proved to be due usually to streptococcus from a distant focus of infection. The authors think that the conclusion seems warranted that fibrocystic degeneration of the ovary, even in the absence of previous acute infection, is due commonly to a low grade hematogenous infection by streptococci having affinity for these two structures, and further that while excision and resection of ovaries is indicated in some instances, it should no longer be done without due regard to the existence of chronic foci of infection, which may serve not only as the place of entrance, but also as the place for the bacteria to acquire the pecu-

liar properties necessary to infect the ovary. The results in one of the cases reported suggests that the eradication of primary foci of infection in this type of patient may in some cases prevent the premature sclerotic degeneration of the ovary.

2. The Etiology of Common Colds.—George B. Foster, Jr., during the past winter has succeeded in confirming Kruse's observations, namely, that though he was unable to demonstrate living organisms in the filtrates from nasal secretions of those suffering with coryza, he found evidence that the causative organism should be classified with the filterable viruses. The results of the writer's recent investigations indicate that from the nasal secretions of persons, who exhibited the characteristic symptom of acute coryza, there has been cultivated *in vitro*, a living virus, and that Berkfeld filtrates of subcultures of this virus are capable of producing symptoms of acute cold in healthy persons. The author concludes that from the experimental evidence presented common colds—of a certain type at least—are infectious; that the causative virus occurs in the nasal secretions, and that this virus is capable of passing through a Berkfeld N filter which has proved impervious to ordinary bacteria. These observations confirm the belief in the transmission of colds from the infected to others through "droplet infection" or other means of direct or indirect contact. However, in the absence of ocular proof that microorganisms, definitely recognizable as such exist in the cultures, the writer reserves the assertion that a virus has been cultivated until additional evidence may accrue.

3. Metabolism in Insanity.—Francis X. Dercum states that it has become increasingly evident that in approaching the problem of the pathology of insanity, we are obliged to turn our attention more and more to basic physical, chemical, and biological facts. After discussing somewhat at length cell structure and cell metabolism he calls attention to Abderhalden's discovery that the serum of pregnant women always contains defensive ferments against placental protein, and that Fauser, realizing that the Abderhalden method must prove of great significance to psychiatry, has studied 250 insane and thirty non-insane persons. His results may be briefly summarized by the statement that defensive ferments were found in all cases in which organic changes existed, while in purely functional cases, such as hysteria, manic depressive insanity and paranoia, all examinations were negative; this was also the result in normal persons. The fact that in manic depressive insanity no lysis was ever found proved frequently to be of value in the differential diagnosis from dementia praecox, the diagnosis being confirmed by the further clinical observation of the cases. Similar results have been achieved by others and the facts revealed by the Abderhalden method appear to justify the following conclusions: (1) In all cases in which either as a result of defective or aberrant organization, or of other disease, abnormal substances find their way into the blood, defensive ferments are evoked. (2) The ferments produced by the defense reaction are frequently injurious to substances other than those which gave rise to them. Notably is this the case in the instance of the cortex in dementia praecox, and perhaps also in paresis. (3) In cases in which no defensive ferments can be found, it is safe to infer that the affection is one unattended by organic changes and that it belongs to one of the purely functional groups, namely, to manic-depressive insanity or to the psychasthenic psychoses. (4) Ferments may be absent in late organic or terminal cases, as in terminal dementia praecox; when the disease has run its course, a time may be reached when poisonous substances are

no longer thrown into the circulation, and in consequence defensive ferments no longer formed. (5) The toxicity in manic-depressive insanity and in other functional states appears to be due to a quantitative change rather than a qualitative change in substances normally present. In all instances, however, the symptoms are due to toxic agents, for substances in excess or abnormally deficient have all the value of poisons. In discussing the hormones the writer states that an internal secretion may be changed or perverted, and when this happens it will lead to the formation of defensive ferments, just as in the case of a foreign substance introduced from without. In dementia praecox we have an instance of such a perverted secretion, namely, a qualitative change in the sex gland. Not only is there, in addition, the development of defensive ferments injurious to the cortex, but there are also present symptoms indicating that these ferments react on the sympathetic and autonomic nervous system. Among other symptoms are such as are referable to the circulatory apparatus, to the digestive tract, and to other very special forms of apparatus, such as the iris. Such phenomena are quite frequent in mental affections other than dementia praecox, and it is quite probable that they are always the result of the action of toxins on the sympathetic and autonomic nervous system. In closing the author suggests that in approaching the pathology of insanity the investigator should study the physics and chemistry of the colloids, he should investigate the interaction of the colloids among each other, both physical and chemical, that is, he should investigate the subject of ferments, and apply the facts acquired to the field opened by Abderhalden and Fauser, and he should include in his studies the actions of the ferments, toxins, or hormones, on the sympathetic and autonomic nervous system and under these circumstances and under given conditions, the reactions of the glands of internal secretions. Finally, he may study the brain tissue itself, but he must remember that the pathology of insanity is not a gross pathology.

1. Nervous and Other Medical Disorders as Seen at an Eye Hospital.—James Taylor emphasizes the enormous importance of ocular and visual signs and symptoms as indications of general disease. He has had unique opportunity at the Moorfields Eye Hospital for seeing cases which illustrated this. In reviewing the cases seen during the past five years he finds that by far the largest group, 233 in number, has comprised those who came on account of failing vision, and in whom this failing vision was found to be associated with optic atrophy. In the great majority of these cases the optic atrophy was found associated with other conditions. In over 200 of these cases there were definite signs of tabes or general paralysis of the insane, sometimes only the Argyll Robertson pupil, sometimes only the absence of knee-jerks and lightning pains, sometimes both these conditions, occasionally gastric crises. This series of cases confirms what has long been known, namely, that ataxy rarely occurs in cases of tabes with optic atrophy. In only two of these 200 cases was ataxy complained of. In a few of these cases the optic atrophy

was the result of retrobulbar neuritis; the reason there were so few of these cases was that usually other signs indicative of interference with the motor system preceded the ocular or visual signs. Optic atrophy was also present in a class of patients in which there was evidence of lesion at the optic chiasma, and in a few instances it was a toxic one, the result of tobacco, often with the addition of alcohol. The next largest class of cases were those that came because of some defect in the ocular movements. One would expect that diplopia would have been complained of in all these cases, but this was not so, for in a certain number of cases of third nerve paralysis, ptosis has been the first sign. Of these cases of ocular paralysis the writer has seen sixty-two during the period referred to and in by far the largest number the third nerve has been affected. In some of the cases of third nerve paralysis there have been definite signs of tabes; in most there has been good reason to suspect syphilis. Another condition causing diplopia is known as myasthenia gravis. Of such cases the writer has seen thirteen during the past five years. This disease is characterized by the greatest variability in muscular weakness and this would account for its having been regarded at one time as hysterical, though it often ends fatally. Myasthenia gravis should always be suspected in patients having this form of ocular weakness. Diplopia also occurs in Grave's disease, and much more frequently than is generally recognized, but the writer has only once known a patient with Grave's disease to come for advice on account of diplopia, though he has had thirty-one cases of this disease during the past five years. Of these four occurred in men and were well marked and unmistakable in every other respect, but showed no enlargement of the thyroid; on the other hand, goitre in women suffering from Grave's disease was extremely common. The writer has only once seen optic atrophy in Grave's disease. In cases of intracranial tumor ocular paralysis is frequently present, and in such cases the defects in ocular movements are frequently valuable indications as to the site of the tumor. Indirect pressure, resulting from ventricular distention, usually affects in a marked way one or both sixth nerves. In this series of cases there were forty-seven albuminuric and fifteen of glycosuric retinitis. In the great number of albuminuric cases the retinitis has been merely an incident, but often the first one which has caused the patient to seek advice. The writer further makes observations on twenty-two cases of hemopia, eleven of which were due to either valvular heart disease, or hypertrophied heart, or were the result of syphilitic vascular disease. The remaining thirteen could not be accounted for on these grounds or by the state of the kidneys; on twenty-six cases of retinal embolism and thrombosis, and thirty-eight cases of optic neuritis; this small number seems to him most unusual when it is recalled that during this same period he saw 233 cases of optic atrophy. He warns against jumping to the conclusion that all cases of optic neuritis indicate the presence of an intracranial growth. In closing the author urges upon ophthalmic surgeons the need for a broad general basis from which to work.

2. "Camp Jaundice" and the Paratyphoid Epidemic at the Dardanelles.—A. Sarrailhé and J. Clunet comment upon the conditions under which this epidemic had its inception, describe its course, and discuss its clinical features and bacteriology. They find that camp jaundice always appears under the same conditions, tired troops, restricted space, imperfect feeding, and unfavorable climatic conditions. In most instances it appears during an epidemic of febrile gastric derangements, or else it follows the latter; more rarely it immediately precedes it. Early in this epidemic

paratyphoid B was isolated on 102 occasions and the typhoid bacillus on thirty occasions, but no paratyphoid A. Later in the epidemic an atypical bacteria presented itself which the writers have designated paratyphoid D. They remark that alongside of febrile forms where jaundice appears as a simple complication of septicemia a large number of attenuated forms are observed in which the fever is of short duration and even of forms completely apyretic, which might be confounded with ordinary catarrhal jaundice. To the writers the most interesting phenomena were the persistence of coloration of the stools, the absence of pruritus, the albuminuria and urobilinuria associated with the elimination of the pigments through the urine, the diminution of the globular resistance and the association of the affection of the gall bladder and liver. While the bacteriological study is by no means complete the following facts may be deduced: (1) The characteristics of the germ cultures and of their serum reactions vary directly as the diminution in virulence of the epidemic and with the frequency of the hepatic localizations—cholecystitis and jaundice. (2) More than one-half of the blood cultures practised during the two first days of jaundice are positive. (3) The germs isolated in the febrile jaundice attacks and in the febrile gastric derangements without jaundice during the same period appear identical. (4) These germs seem to have a selective action upon the liver, but may give rise to clinical manifestations in other viscera.

1. A Case of Bilateral Motor Apraxia with Disturbance of Visual Orientation.—S. Smith and Gordon Holmes report this case because it is only within recent years that the motor disturbance known as apraxia has claimed attention and because even yet very few well-marked instances have been described in the English literature. They state that the condition is characterized by inability to combine simple movements into purposive acts. In the case here described the apraxia followed a wound in the head by a shrapnel bullet. The intellectual state of the patient was moderately good; there was no affection of sensation and no form of agnosia. Vision was affected, but it stood in no causal relation to the apraxia. There was no paralysis, and the range and the power of the movements of all the patient's limbs were normal. The right knee-jerk was, however, brisker than the left, and the plantar response on this side was extensor. Tactile and painful stimuli were appreciated naturally and correctly localized everywhere, and there was apparently no loss in sense of position and no optic neuritis. In spite of this the patient was unable to perform certain purposive acts and to use objects and instruments which were familiar to him and which he recognized correctly. With constant practice and steady application he relearned simple actions of which he had most need, as lighting a cigarette. There was at no time any trace of tonic perseveration or that difficulty in relaxing

muscles that he had contracted voluntarily, which has often been associated with apraxia, and it was only in the early stages of his illness that he showed any tendency to repeat actions which he had just performed when told to do something else. The most striking feature with reference to his visual disturbance was his inability to look straight at any object held before his face; he generally stared open-eyed in the wrong direction. His visual memory was not seriously affected, but his visual retentiveness, on the other hand, was very defective. There seemed to be a failure of objects that stimulated the peripheral parts of the retinae to excite attention and the appropriate ocular movements. In discussing the site of the lesion the writers think that if the ball took its direct course between the point of entrance and of exit, as is usual in similar wounds, the brain was entered in the posterior and upper part of the right supramarginal gyrus, and there is reason to believe that the track passed through the dorsal part of this hemisphere, perforated the falx $1\frac{1}{2}$ cm. dorsal to and 1 cm. in the front of the posterior margin of the splenium of the corpus callosum, entered the left hemisphere in this position, passed just dorsal to Wernicke's field in front of the knee of the optic radiations, and made its exit in the inferior part of the left supramarginal gyrus in front of the posterior end of the fissure of Sylvius. In several of the recorded cases of apraxia the lesion corresponded more or less closely in position to that present in this patient.

4. **Acute Gangrenous Cholecystitis.**—John Morley and F. Battinson Smith report this case, which occurred among the troops during the epidemic of jaundice in Gallipoli in 1915. Cases of ascending infection of the bile ducts, liver, and gall bladder became extremely common at that time and this case appears to be of special value, since it shows that in a patient inoculated against typhoid fever a paratyphoid organism in the early days of infection may ascend from the intestine to the gall bladder and there settle without causing more than an initial and indefinite epigastric tenderness associated with anorexia and headache; that later its numbers and virulence may be so increased as to cause actual gangrene of the gall bladder; and that, therefore, it is not improbable that from the gall bladder, in cases of cholecystitis, a subsequent descending infection of the common bile duct with consequent jaundice may take place. This may explain numerous cases of jaundice which give a history suggesting a previous cholecystitis. William Campbell, in commenting on this case, says that it is likely that a close study of those organisms whose growth is known to be favored by bile may help to enlighten us as to the cause or causes of the jaundice with pyrexia, which occurred in the Dardanelles, and, although jaundice is not a common complication of typhoid fever, it is possible that the paratyphoid infections may play a much more important part than the *B. typhosus* in the production of febrile jaundice. He says further that the carrier problem also suggests itself and that for various reasons it seems highly improbable that the cases of jaundice occurring in the Gallipoli epidemic have, by any means, a uniform specific bacterial cause.

6. **Paracholera.**—Aldo Castellani recalls that he introduced the term paracholera some years ago to denote cases which, though hardly distinguishable from cholera clinically, are due to vibrios somewhat different from true cholera. The most important of these vibrios are the Finkler and Prior's organism, Pasquale's *Vibrio massachusetts*, Ruffer's vibrios, the *Vibrio kegalensis*, which the writer has isolated from cases in Ceylon, clinically scarcely distinguishable from cholera.

This germ is microscopically and culturally very similar to *V. cholerae*, but is not agglutinated by true cholera serum in dilutions higher than 1 in 10 or 1 in 20; cholera vibrio is not agglutinated by *V. kegalensis*. The writer has been unable to reproduce the disease in the lower animals by feeding experiments, but considers that since the vibrio was present in the stools of the patients in enormous numbers and was the only species of vibrio present, it is probable that it is pathogenic.

Treatment of the Möller-Barlow Disease.—Peiper begins by stating that a surprisingly large number of general practitioners appear to ignore the existence of this severe and perilous affection. The latter is not of frequent occurrence and may pursue an abortive course. Whoever is ignorant of the nature of the disease will very likely in the absence of a careful examination fail to make a correct diagnosis. The author now relates a personal case in which he illustrates the hemorrhagic swelling of the gums and subconjunctival extravasations. The infant, aged ten months, had been living on milk which was sterilized at high temperatures with the view of preventing summer diarrhea. Eventually—after some five months of this diet—its health had begun to fail. It was found to be highly anemic, with swollen gums and tenderness low down in the femora. Mild rickets co-existed. No attempts had been made to give the infant extra food. The pains in the limbs suggested a rheumatic affection at first, while later periostitis or osteomyelitis was simulated. The scorbutus-like symptoms then appeared and served to prevent a diagnostic error. When the case reached the author he excluded in succession rickets, rheumatism, osteomyelitis, coxitis and Parrot's paralysis. The x-ray then readily revealed the subperiosteal swelling, so that the diagnosis was assured. If the disease escapes recognition or if the diet is not varied a fatal termination occurs, with bloody enteritis or final pneumonia. The mortality is high and the treatment is at the same time simple—an ideal affection for the medical man to show his powers for good. Spontaneous recovery is of doubtful occurrence. The disease yields to diet and may relapse if the latter is not maintained for a sufficient period. There is, no doubt, some predisposing element, for the disease only attacks bottle-fed babies. Oversterilized milk, ordinary boiled milk and prepared infant foods are chiefly to be accused. A mere diet of uncooked food is sufficient to cure and is at the same time the sole condition for cure. The best raw food is human breast milk, which should be used if possible in all severe and complicated cases; but the extreme sensitiveness of the infant makes application to the breast very difficult. Next in merit would come the best raw laboratory milk or its equivalent obtained as soon from the dairy as possible. At first the infant has no appetite and must be fed with the spoon. Soon it feeds with the greatest avidity from the bottle. All the drawbacks of raw milk may assert themselves so that dilution with water or cereal decoctions must be tested. If raw milk is impossible it may be brought just to a boil—to the rise of the first bubbles—and then offered to the infant. As soon as the milk problem is settled the infant should be placed at once on so-called antiscorbutics, beginning with orange juice. The fruits and berries in season may also be used in the same way. The raw scraped pulp of apples, pears, bananas, etc., and fruit sauces (stewed fruits) and finally entire fruits may be eaten. Home-made meat juice is also an integral part of the diet. Vegetables, presumably

stewed, may be used if the other foods are not readily taken, and in time should form part of the diet—spinach, cauliflower, turnips, potatoes, asparagus tips. The disease attacks principally the children of the well-to-do.

Functional Tests of the Kidneys with Substances Alien to the Body.—Treupel says we can give a certain amount of work for the healthy kidneys to do and form some idea of the task imposed on them and of how they perform it. If the kidneys are diseased we cannot expect such accuracy, yet can obtain information upon which a judgment can be based. Tests with alien substances are chiefly color tests. Solutions are injected into the buttocks and should appear in the urine within a stated time. Phenolsulphonephthalein should be injected into a vein. Potassium iodide alone may be given *per os*. Of the tests in use by the author one only—sodium salicylate—is a reaction test. A general diagnostic test is, however, incomplete in the absence of a cystoscopic differentiation of the kidneys, which also gives a more prompt result. The author at great length discusses the results of Schlayer and conclusions drawn therefrom and is averse to applying these straightway to mankind. They are said to be verified in certain types of nephritis, although this has been disputed by von Monakow. The author thinks that individual cases of nephritis do not sufficiently resemble one another to justify a generalization in respect to insufficiency tests. Nevertheless Schlayer's recommendations are often useful in clearing up the diagnosis and prognosis of obscure cases. The technique is as follows: Patient is put on a uniform diet, including fluids, with a not excessive amount of salt; he then receives 1600 c.c. of water which the normal man should excrete in twelve hours. One-half a gram of potassium iodide given by the mouth should all pass through the body in from fifty to sixty hours at the most in the healthy subject. Then 10 grams of common salt are given and the urine tested by Schwartz's method for the salt content. Of milk sugar 20 c.c. of a 10 per cent. solution injected into a vein should be excreted in six hours at the most. The urine is tested with the polarimeter.

Deutsche medizinische Wochenschrift.

Feb. 17, 1916.

Cachexia of Hypophyseal Origin.—Simmonds two years ago reported a case of a peculiar, severe and persistent cachexia which ended fatally after many years. Autopsy revealed no lesions save a high degree of destruction of the hypophysis. It was believed at first that the case was a typical deficiency disease. This view has been borne out in part by the experience of another case, as follows: Male, fifty-eight; always healthy until two years ago, when he became permanently weak, thin, and pale and suffered much from cold. A thorough examination revealed no organic disease. Diagnosis of occult cancer. Death occurred from pneumonia. Section revealed recent pneumonia and pericarditis. No evidences of pernicious anemia. Two tumors of the size of a hazelnut had replaced the hypophysis and its pedicle, causing great dilatation of the sella turcica. The two growths together resembled an hour glass. Microscopically they were basophile adenomata. No trace of hypophysis substance was left. The optic nerves were not compressed. The question is: "How could a benign tumor cause such a general disturbance?" Another question in reference to the absence of acromegaly can be readily answered because in the latter only the oxyphile cells of the hypophysis are involved. There were evidences of a lesion of the neurohypophysis in a distinct atrophy of the testicles and prostate, spermatogenesis having ceased. There

was also a thinning of the beard and pubic hair. However, the patient retained his full masculine habitus. The author has also seen a third case in a girl, aged nine, who began to lose her appetite and to emaciate without apparent cause. Later there was polyuria. The diagnosis was occult tuberculosis. Autopsy revealed only a basophile adenoma of the hypophysis. All three cases agreed among themselves, although in the very first one mentioned the destruction of the hypophysis was due to an old embolic process. The cachexia could have but one origin—the loss of the hypophysis—as the result of a very slowly developing lesion. As a rule a lesion of the hypophysis is seldom an isolated manifestation. Apparently a very small portion of the gland can functionate, the cachexia appearing only when the gland is entirely destroyed.

Noma.—Peiper in an article on the treatment of infections of the buccal cavity in nurslings, touches upon noma, a condition not so often seen in young infants as in those of three years old and upward. It is seen rarely in healthy children, but is much more common in the cachectic and as a complication of acute infectious diseases. It is a for the most part unilateral gangrene of the cheek close to the angle of the mouth, at first circumscribed, hard and sensitive. The corresponding mucosa is similarly affected. Blebs form, the external portion of the lesion softens, and the process rapidly spreads peripherally. The cheek becomes much swollen and the lymphnodes enlarge. There is an ichorous, bloody, very fetid discharge and severe sepsis develops. Nothing is known of the cause, and it has never been shown that a microorganism is responsible, although this is naturally inferred. The affection is hardly contagious and isolation is advised only because of the distressing odor. The author who has seen numerous cases would never temporize, but excise the gangrenous area and apply the cautery as soon as possible.

Synthetic Oxytocics.—Jaeger has made many trials of B-imido azolyethylamin, a constituent of ergot, which may be termed for short B.I. He found that it possesses oxytocic properties much like those of pituitrin if given in high dosage. But such dosage is very apt to cause unpleasant collateral manifestations. The author next combined it with another ergot constituent, to wit, P-oxyphenylethylamin (P.O.) and obtains now what is called the "full action" of ergot, which is a drug of known inconstancy when given in its more native forms. The unpleasant collateral activities of B.I. are entirely eliminated. The author has tested combinations of different proportions until he obtained an optimum. Of 100 women tested the result was negative in eight, which suggests somewhat the inconstant action of ergot *per se*. The remedy is synthetic throughout, both the active principles being synthetizable. It cannot be used by the intravenous method, but is given either by the subcutaneous or intramuscular route. The author does not seem over-enthusiastic regarding it. The main question is "can it replace the older preparations of ergot?" Since digitalis has undergone a similar crowding out by its numerous derivatives, this synthetic may displace ergot.

The Surgical Significance of Constipation.—If constipation develop in an adult, exclude intestinal neoplasm before treating the condition as functional. Carcinoma of the sigmoid, for example, may exist for some time without any other symptom than constipation until obstruction or perforation suddenly develops. Sigmoidoscopy or bismuth x-ray examination will usually locate such a condition. These diagnostic measures should be employed, therefore, in cases of recent adult constipation of unknown cause.—*American Journal of Surgery.*

Book Reviews.

THE PRIMARY LUNG FOCUS OF TUBERCULOSIS IN CHILDREN. By Dr. ANTHON GHON, Professor of Pathological Anatomy of the German University in Prague. Translated by D. BARTY KING, M.A., M.D., M.R.C.P. Price 10/6 net. London: J. & A. Churchill, 1916.

THIS book deals with a subject which of late has aroused a good deal of interest inasmuch as at the present time more attention is being paid to the prevention of infection in childhood and contact infection of the adult is considered of secondary importance in the etiology of tuberculosis. The post-mortem material, which forms the basis of this work, originated in St. Anne's Hospital in Vienna.

In the first chapter the author cites a number of cases with lung focus and changes in the neighboring organs and comes to the conclusion that in 35 per cent. the adjoining lymphatic glands are involved, and that cases of lung focus without other changes are exceedingly rare (0.54 per cent.) In the second chapter an interesting group of 170 cases of primary foci are enumerated in which were found 123 cases with one lung focus each, twenty-five with two foci each, eleven with three foci each, and six with more than four lung foci each. The author devotes the third chapter to appearance and size of the lung focus which study reveals the fact that small sizes predominated and the highest number consisted of lung foci of the size of peas. The conclusions in the chapter show that practically all the sections had lung foci, but that, generally speaking, the anterior upper portions of the upper lobes and posterior lower portions of the lower lobes showed the greatest number, while in the middle lobe of the right lung these same sections seemed to be equally affected; also, that the right lung showed more foci than the left, and that finally the right upper lobe contained the largest number. The subsequent chapters are descriptions of more complicated findings—scars, adjoining lymphatic glands, and caseation, which study led the author to conclude that everything tended to show that the primary lung focus was never formed after the perforation of the altered bronchopulmonary or tracheobronchial lymphatic glands, but was always present before.

The whole book represents an interesting study and confirms the conclusions at which Knopf of New York arrived as the result of similar work (MEDICAL RECORD, Jan. 8, 1916), namely, that in childhood the primary infection of the lungs represents the usual form of tuberculous infection. If any criticism of the book can be made, it might be that the author contented himself in his anatomical researches with macroscopical findings only and never resorted to the microscope, which very often shows a tuberculous lesion which the naked eye had failed to discover. For those interested in this subject, the book cannot be too highly recommended.

A REFERENCE HANDBOOK OF THE MEDICAL SCIENCES, Embracing the Entire Range of Scientific and Practical Medicine and Allied Science. By Various Writers. Third Edition Completely Revised and Rewritten. Edited by THOMAS LATHROP STEDMAN, A.M., M.D. Complete in Eight Volumes. Volume Six. Illustrated by Numerous Chromolithographs and Four Hundred and Ninety Half-Tone and Wood Engravings. Price, \$7.00, cloth. New York: William Wood and Company, 1916.

THE reviewer eagerly awaits each new volume of the Reference Handbook in keen expectation of finding among the titles of articles some that are entirely new in the reference literature of medicine. There are a number of these articles in Volume Six which has just appeared. Among these is one on "Pseudotuberculosis" of the Lungs, which is defined as a blanket term including those forms of tubercle formation in the lung that simulate the type disease but are not due to the tubercle bacillus. The article on Medical Licensing Boards is a particularly helpful digest of all information available as to the requirements for practice in the different States in this country and in the different foreign countries, Abyssinia and Zanzibar included. In both of the last there are no restrictions upon practice, a fact which may be of some comfort to those of our students who fail to pass their State Board examinations. Naval Hygiene and Naval Medical Service are discussed in two articles of twenty-two and six pages, respectively, which articles are commended to those who are interested in the campaign of national preparedness. The titles of the present volume range from

Ligation of Arteries to Ozena. Among them appear important articles on the Liver, Lungs, Lymphatic System, Meninges, Mental Diseases, Metabolism, Muscle, Milk, Nephritis, Nerves, Neuroses, Nose, Old Age, Occupational Diseases, Ophthalmometry, Ophthalmoscopy, Optometry, Otitis Media, and Ovaries. There are interesting articles on Lip Reading, Massage, the Microscope and Its Accessories, Nanism and Organotherapy. The articles on diseases of the liver comprise a section of thirty-eight pages. Abscess of the Liver is discussed in an admirable manner, but there is ground for criticism in the fact that among the twenty-four references tabulated at the end of this article there is none published later than 1904. The section on Mental Diseases takes up sixty-six pages and includes separate articles by different authors on Classification, Examination and Diagnosis, Etiology, Pathology, Prognosis, Symptomatology, and Treatment, and also a special article on Dementia Præcox. The subject of Tuberculosis of the Lungs is handled in an eminently practical manner, the newer method of treatment by artificial pneumothorax being described in ample detail. There is a separate article on the Operative Treatment of Nephritis. The Neuroses are discussed under the separate headings of the Nasal, Pharyngeal, Occupational, Traumatic, and Sexual. Among the last there are described, apparently for the first time in medical reference literature, "Clitorism" and "Dyspareunia in the Male." Among the entertaining features of this volume are the short medical biographies, many of which are illustrated with a wood-cut portrait. On the whole, this volume maintains the standard already referred to in the reviews of the former volumes, namely, readability, and value for both reference and study. The illustrations are numerous and of artistic treatment, and the other mechanical features leave nothing to be desired.

AMERICAN SEWERAGE PRACTICE. Volume III. Disposal of Sewage. By LEONARD METCALF and HARRISON P. EDDY. Price \$6.00 net. New York and London: McGraw-Hill Book Company, 1915.

THE purpose of this volume is twofold: First, to explain in simple, non-technical language the nature of sewage and the changes that take place in it when it is subject to different conditions, and, second, to describe the structures designed to produce these conditions, in order that the character of the sewage may be changed to the desired extent before it finds its way into some body of water. The authors describe the important advances in the art of sewage treatment that have been made during the past twenty-five years, and express the belief that further advances will continue to be made. Among the topics considered are the following: Progressive steps in sewage treatment; meaning of chemical analyses; bacteria and their relation to the problem of sewage disposal; plankton; composition of sewage; theories of sewage disposal and treatment; sewage disposal by dilution; grip chambers; racks; cages and screens; sedimentation, straining and aeration; tanks for sludge digestion; chemical precipitation; sludge; contact beds; trickling filters; intermittent sand filtration; irrigation and agricultural utilization of sewage and sludge; automatic apparatus for dosing; disinfection of sewage and sewage effluvia. There are 230 illustrations and 205 tables. The authors handle their subject in a most thorough and comprehensive manner and have produced a volume which will prove useful to everyone interested in the subject of sewage disposal.

HOSPITALS AND THE LAW. By EDWIN VALENTINE MITCHELL, LL.B., of the Faculty of the College of Law, University of South Dakota. Price, \$1.75. New York: Rebman Company, 1915.

THOSE readers who are familiar with "The Doctor in Court" by the same author will need no special persuasion to become interested in this book. It was written "to supply a short analysis of the general propositions of law relating to health institutions, and to make it readily comprehensible to those who are professionally or otherwise interested in such establishments." It is an admirable work, much condensed and replete with illustrative cases which make the meaning of the law and the decisions as plain as it could be made to the lay mind. Our only criticism would be that the author has devoted so little space to the question of autopsies, one which, in a large general hospital, probably arises more frequently than any of the other problems which he mentions. It is a very interesting volume and a valuable one.

PRINCIPLES OF GENERAL PHYSIOLOGY. By WILLIAM MADDOCK BAYLISS, M.A., D.Sc., F.R.S., etc., professor of general physiology in University College, London. With 259 illustrations. Price, \$6.00. London and New York: Longmans, Green and Company, 1915.

TIME was when the English physiologists led the scientific world by their discoveries, but with the restrictions imposed by the antivivisection laws on research in England and the rise in medical science in Germany under the leadership of Ludwig and his school, the laurels passed across the channel. Of late years a renaissance in physiological investigation has made itself felt in England, however, despite the stupid prohibitions on animal research there, and this book is one of the finest fruits of the new school. The breadth of view with which the author has approached his subject gives to the volume an extraordinary interest. He has, indeed, dipped with comprehensive grasp into the whole storehouse of science and seized many armfuls of interesting lore, so that at whatever page the volume opens one feels constrained to stop and read. After all, general physiology does mean life, in its more specialized sense, and there is hardly a department of science that is not touched upon in the modern study of its phenomena. Much of this material must, however, be sought for in sources quite remote from the general literature of biology and physiology, and it is with the idea of describing in detail and rendering more easily accessible this borderland of knowledge which surrounds the more precisely delimited provinces of biology and physiology that the present book was written. Accordingly, one finds much valuable matter devoted to such topics as energetics, mathematics in physiology, the effect of temperature on the rate of reaction and on equilibrium, the many phases of adsorptive phenomena, the colloidal state, the permeability of membranes and other aspects of osmotic processes, electrolytes and their action, catalysis, mass action, equilibrium and reversibility, etc., to choose but a few from the many subjects discussed. Naturally, the usual physiological processes, such as digestion, secretion, nerve action, respiration, etc., are also fully treated and illuminated by new side lights from the more abstract sciences. The book will primarily be useful to teachers in almost any field of medicine or biology, but will also be of great interest and value to advanced students or those having at least some knowledge of physics, chemistry, and biology. From the literary standpoint it is delightful and possesses qualities of style not often seen in scientific treatises. The historical introduction to the different subjects and the numerous portraits of men who did important work in developing new fields of research also contribute greatly to enliven the pages of a work that is unique in its scope and in the completeness with which the ground is covered.

THEORY AND PRACTICE OF BLOODLETTING. By HEINRICH STERN, M.D., LL.D.; Visiting Physician St. Mark's Hospital; Consulting Physician, Methodist Episcopal (Seney) Hospital; State Hospital at Central Islip; Deaconesses' Home; Port Chester and Glens Falls Hospital; Founder and Editor of the *Archives of Diagnosis*. Price, \$2.50. New York: Rebman Company, 1915.

THIS is a scholarly monograph on one of the most ancient procedures in the healing art. For many centuries the heroic abstraction of blood was regarded as a panacea for almost all ailments. Like other valuable measures carried to an extreme, it finally fell into disrepute. But within recent years the therapeutic possibilities of bloodletting have again asserted themselves. These possibilities are set forth in the present volume by one who has given the subject considerable study, and who has had exceptional experience in the application of bloodletting and in the development of new methods for its performance. The subject matter of this book is divided into two parts, the first of which deals with the general fundamentals of bloodletting, and the second with the special clinic of local and general bloodletting. Under general fundamentals there are included chapters on historical retrospect, on functional changes following bloodletting, and on the present status of the technique of bloodletting. This technique comprises bloodletting proper and the so-called bloodless methods, such as phlebotomy in which a venous stasis is produced in the extremities by means of inflated elastic cuffs, a certain amount of blood being thereby removed from the circulation without any actual loss of blood to the body. In discussing the func-

tional changes following bloodletting the author emphasizes the rôle which this plays in modifying the molecular concentration of the body fluids, and by a physico-pharmacological action serving as a rational therapeutic agent in the presence of a disturbed osmotic equilibrium, a suspended transudation of blood plasma through the vessel walls, or capillary sluggishness. Under bloodletting proper the author describes scarification, wet cupping, artificial leeching, natural leeching, phlebotomy, and venepuncture. In the section on the special clinic of local and general bloodletting the author discusses only those disease conditions in which this procedure produces definite results, such as pneumonia, emphysema, plethora, edema of the lungs, certain diseases of the heart and blood vessels, acute and chronic uremia, puerperal eclampsia, ectogenous intoxications, chlorosis, cerebral hemorrhage, hemiparesis, and certain skin diseases. While recognizing the wide sphere of usefulness of bloodletting, the author maintains a justly conservative attitude with respect to its therapeutic limitations. He reviews the literature of the subject in a thorough manner, detailing the work, among others, of Mackenzie, v. Jaksch, Lilienstein, Bajinsky, Eichhorst, Grawitz, Jürgensen, Osler, and Sacharjin. The paradox of the abstraction of blood as a remedial agent in chlorosis is explained on the basis of the well recognized fact in physiology that the sudden loss of blood serves as a potent stimulus of blood regeneration. There are many other phases of the therapeutic application of bloodletting that are discussed at length in this book, which may be recommended to the general practitioner as one that will repay reading. It is a substantial contribution to medical literature.

THE OBSTETRICAL QUIZ FOR NURSES. A Monograph on Obstetrics for the Graduate and the Undergraduate Nurse in the Lying-in Room. By HILDA ELIZABETH CARLSON. New York: Rebman Company.

IN this quiz-compend (or monograph, as the author prefers to call it) will be found such of the facts of obstetrics as a nurse is likely to require. Naturally, the book does not contain as much as the ordinary textbooks on the subject which have been written for nurses and which we have noticed from time to time in these columns; but what is here presented is, as a rule, accurate and well selected. The language is often capable of improvement, and the proper names have suffered rather severely. Thus, we find Hagar and Hagars, but not Hegar; Pier's treatment; Kelly pad and Kelley pad; Crede, invariably without the accent; Deuncé, and the Jardin des Plantes. Such expressions as the following should be corrected: Parasitis stomititis, labias, mastitis of the breasts, the use of the forceps are indicated, the Eustachian valve of the foramen ovale. We have not been able to find anything on the pernicious vomiting of pregnancy, an important omission.

THE NEW PUBLIC HEALTH. By HIBBERT WINSLOW HILL, M.B., M.M., Ph.D. Late Director, Division of Epidemiology, Minnesota State Board of Health, and later Executive Secretary, Minnesota Public Health Association; now Director Institute of Public Health and M.O.H. of London, Canada; Professor of Public Health, Western University. Price, \$1.25. New York: The Macmillan Company, 1916.

THIS book is a collection of articles which the author prepared at the request of the Minnesota State Board of Health for the purpose of showing the modern conception of public health for the information of both the medical profession and the laity. These articles were published in the *Journal-Lancet* of Minnesota and given to 1100 newspapers in this country and 50 in Canada. The author describes the old idea of public health as concerned chiefly with environment or living conditions; the new with the individual as the source of infection. He points out that thus far public health has aimed chiefly to control infectious diseases; the new public health must extend its activities to education in hygiene in all its phases. This must be done through the grade schools if the large body of the population is to be reached. While the author has presented nothing new to the student of the science of public health, his book serves to emphasize the need for more general information on this subject if the public is to be awakened to a realization of the fact that science has furnished the knowledge whereby infectious diseases may be eliminated, but if this happy condition is to be realized it remains for governmental authority and the public to apply this knowledge.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held March 16, 1916.

THE PRESIDENT, DR. WALTER B. JAMES, IN THE CHAIR.

Chronic Osteoperiostitis from Infection by the Streptococcus Viridans and Other Organisms: A Clinical Study of the Origin of Certain Obscure and Obstinate Pains of Common Occurrence.—Dr. CHARLES L. DANA read this paper. (See page 765.)

The Pathology.—Dr. THOMAS W. HASTINGS opened the discussion on Dr. Dana's paper. He called attention to the pathology as it related to the supposed causes of periostitis, and mentioned the fact that acute suppurative periostitis was not under consideration. He referred to the fact that organisms not usually considered as causative agents had been described in chronic periostitis, as the gonococcus in a case reported by Bloodgood. Periostitis which became subacute or chronic as a rule was due to tuberculosis or syphilis and were not the cases referred to by Dr. Dana in his paper. Cases of this type, that was chronic periostitis not due to tuberculosis and syphilis, were often puzzling as to their cause. In studying patients with chronic deforming arthritis it was frequently found that not only were the joints involved, but frequently that this involvement was the least important factor in relation to the patient's pain and other symptoms. In chronic infectious arthritis the involvement of tissues about the tendons at their attachments to the bone and to the muscles, and apparently the involvement of the periosteum near the extremities of the bones, caused more disability and pain than that of the joint itself. After careful observation in many arthritis cases it was apparent that the statement of Garrod was well borne out. This worker observed that sooner or later similar lesions, detected by x-ray findings, would be found in both gonococcus and non-gonococcus forms of infective deforming arthritis; likewise, as mentioned by Dr. Dana, similar symptoms and x-ray findings, due to a perisynovitis, a neuritis and a periostitis, were not necessarily caused by the *Treponema pallidum* or the tubercle bacillus, but might be due to *Streptococcus viridans* or gonococcus. Dr. Hastings mentioned that there was no proof of a histological or pathologico-anatomical nature for a periostitis due to *Streptococcus viridans*, but that the proof depended upon bacteriological and immunological methods. A larger number of cases of periostitis than had been referred to by Dr. Dana (many of them associated with chronic deforming arthritis) had been found to be due to *Streptococcus viridans*, which was closely related to the *Micrococcus rheumaticus*. Many cases of periostitis and peritenosynovitis must be accepted as of rheumatic (*Streptococcus viridans*) origin. Such cases seldom came to autopsy. Dr. Hastings said that he knew of only four cases of patients that died after long-continued illness, and it was not possible to obtain a post mortem, or even any of the tissues for examination. In any conditions of infection, however, the cause of the infection might be proven by finding, first, the foci of infection and isolating bacteria therefrom; second, by obtaining the bacteria by culture from the circulating blood; third, by carrying out certain blood tests to detect the presence of specific immune bodies (the complement fixation test of Bordet) for the invading organism; and, finally, by obtaining specific focalized reactions in the areas of infection, within six or eight hours after injecting a relatively large dose of specific vaccine, as determined by cultures and blood tests. Careful distinction should be made between the Wassermann reaction and the complement fixation test of Bordet. The Wassermann reaction, as was well known, was not specific in the true sense of the term. The Bordet complement fixation test was specific and therefore much more certainly diagnostic than the Wassermann test. It had been found in the acute stages of infections, for example, such as chorea in acute rheumatic fever, that a *Streptococcus viridans* might be grown from the circulating blood in the early febrile stages of the disease, and later blood cultures would be negative and the complement fixation test positive. In both instances the prognosis as a rule was favorable. In the later days of the same conditions the blood might be overwhelmed with the bacteria, and the blood cultures might again be positive and the complement

fixation test negative. In all three stages the positive blood culture and the positive complement fixation tests were diagnostic. Positive blood cultures early in the disease carried no grave significance, while in the later stages this gave a grave prognosis. These statements were facts generally known, and while they proved the presence of certain bacteria as invading the body generally, did not detect localized restricted areas of infection, as, for example, the periosteum. In cases of periostitis, as in most cases of chronic arthritis, it was difficult to obtain by culture bacteria in the circulating blood, although this had been done infrequently in cases of chronic deforming arthritis. As first proven by Besredka for the streptococcus particularly, and by Schwartz and MacNeal for the gonococcus, positive fixation tests for these two types of bacteria meant that infection had spread beyond the original foci of invasion. While Besredka did not work with strains of *Streptococcus viridans*, judging from his reports, it had been found, as stated by him, that the complement-fixation substance was most readily obtained, and only obtained in large quantities, by injecting animals such as rabbits, intravenously, with *Streptococcus viridans*. Clinically, it was borne out that fixation tests for viridans and gonococcus were positive only when there was evidence of widespread invasion. Also, as a rule, in numerous cases of pyorrhea alveolaris, where there was no evidence of systemic invasion, the complement fixation tests were negative. The proof that diffusely scattered areas of periostitis, with or without chronic arthritis, might be due to *Streptococcus viridans*, consisted of the fact that in cases giving positive complement fixation for *Streptococcus viridans*, the injection of a specific vaccine called forth an acute exacerbation of symptoms in localized areas, known to be involved from the clinical symptoms. It was right to assume that positive growths of bacteria from a focus through which infection might be diffusely scattered throughout the body, with positive complement fixation for the type of bacterium isolated from the focus, and with localized reaction in a focus or foci known to exist clinically, was conclusive evidence for the determination of the nature of infection and for its localization. The complement fixation test would persist positively in the blood for gonococcus and some other organisms after injections into the normal individual of several doses of vaccine. Schwartz and MacNeal found for the gonococcus that 53 days after the last injection of vaccine the complement fixation test became negative. On the other hand they found that the complement fixation test for gonococcus was positive as long as 20 years after the original infection. The same results had been obtained for *Streptococcus viridans* infection with chronic deforming arthritis and in some cases of periostitis. These positive tests persisting for years meant that the infection was sluggishly active, continuously or intermittently, in other tissues than the localized focus. This was well exemplified by syphilis. During the early stages with the primary lesion the Wassermann reaction was, as a rule, negative and became more frequently positive after invasion of the entire body, as evidenced by the appearance of secondaries. The same statement might be applied to infections with gonococcus or *Streptococcus viridans*, the most important conclusion being that the positive complement fixation test meant systemic invasion.

The Radiography.—Dr. LEWIS GREGORY COLE said he would spend but a few minutes in demonstrating a few slides of Dr. Dana's cases, two of which he had examined. Personally, he felt that they should have more definite evidences of lesions which showed directly the point of entrance of the special foci of infection. In both of the cases examined and radiographed by him there was a real periostitis. In many of these cases, however, they did not find any evidence of either tuberculosis or syphilis. It should be remembered that the surgeon and internist should go hand in hand with the radiologist in making a diagnosis of these cases in order to get the best results. Dr. Cole congratulated Dr. Dana in being able to present this subject so well and he hoped that what had been presented would stimulate work along this same line.

The Orthopedics.—Dr. VIRGIL P. GIBNEY said that he was deeply interested in the subject brought before them by Dr. Dana, and it had long been a burning question with him, as it was so closely connected with orthopedic surgery, which included osteitis, periostitis around joints, joint lesions themselves, and the various

painful neuroses one could not always explain. Now, by looking into the mouths of his patients he learned a good deal regarding the condition of the teeth and even all the contents of the oral cavity. When he found a case that puzzled him very much and had puzzled him for a long, long time, he made it a rule to examine the teeth to see if there was not a capped tooth or a receding gum that would call his attention to the need of a radiogram. Such a case was then sent to one or other of the many good roentgenologists in this city for an x-ray of the entire upper and lower jaws. The gentleman in charge of this work at the Hospital for Ruptured and Crippled, Dr. Darling, would always send him the negative as well as the films with his own report of the findings; a duplicate of these was sent to the family dentist, who could decide whether a tooth should be extracted or could be treated successfully. Dr. Gibney insisted on not assuming the responsibility of having the teeth extracted, because he had long since learned that the dentists themselves were able to obliterate these so-called apical abscesses by skillful treatment and thus save the tooth. The charge, therefore, that they were sacrificing teeth unnecessarily was an unjust one. Dr. Dana had asked him to report some cases bearing upon the subject and he submitted the following:

CASE I.—This patient, a girl, 5½ years of age, seen January 8, 1914, had what Dr. Gibney regarded as infectious arthritis of hip of four weeks' standing. She was treated by plaster paris bandage to immobilize, up to March 31, 1915, when his attention was called to some gum boils which she had; she had been troubled with these for nearly a year. The x-rays having failed to show any lesion about the hip, he had the jaws x-rayed and the plates sent to her dentist, who wrote under date of April 6: "In the inferior maxilla the first and second left deciduous molars are in bad condition, the former having an open gum boil; one permanent central normally erupted, the other partially and irregularly erupted, being displaced by the deciduous lateral, which is still firm but should be extracted. I recommended also the extraction of the first and second deciduous molars." The mother called two or three months later that she had taken his advice and that the hip symptoms had disappeared and the child was perfectly well.

CASE II.—This patient was a woman, 64 years of age, seen November 27, 1914. The diagnosis of fungus arthritis was made. Because of weak feet and excessive flesh Dr. Gibney interrogated the term "fungus" and substituted "static"; she had been suffering for about three years with creaking knees, difficulty in getting about, and pains after exercise. He found the molars were capped on the right side and she said she had had an abscess in one of her teeth. An x-ray was taken and the report was that several of the teeth did not have the root canals filled, but the first and second molars, which were crowned, did not have the root canals filled and had an alveolar abscess entirely surrounding their roots; one of these was almost entirely gone from caries. The plates with the full report were sent to her dentist; cultures were not made, but he gave her appropriate treatment, and some months later her husband, in calling him up about another member of the family, said his wife had obtained complete relief and needed no treatment for her knees. Whether the correction of her weak foot, which was a part of my treatment, or whether the removal of the source of infection was the cause of her cure, he was unable to say.

CASE III.—This patient was a gentleman, about 40 years of age, first seen by Dr. Gibney June 10, 1913. He came under his care for flat foot and what he thought was neuritis of the right shoulder. His history was rather interesting. In November, 1911, he had an attack of what he regarded as inflammatory rheumatism, which kept him in bed for about 5 months. Upon getting up his knee was deformed and his feet and shoulders were stiff, and when he began to walk he had marked flat foot with deformity of the great toe. He went to Mount Clemens on crutches, and while there gave up the crutches, as his knee became straight. When I saw him he had a very sensitive great toe joint, a marked hallux valgus and the hips and knees were painful on use. He had some crowned teeth, and upon further examination it was found that he had had a similar attack to the one in 1911 in 1908 and suffered quite as much as he did with this attack just reported. In other words, he had had an attack in 1908, lasting a year and a half; one in 1911,

lasting five or six months, and this light attack in 1913. The radiologist reported Rigg's disease extending down the roots of many of his teeth and two showed evidence of absorption and probably abscess cavity at the root. He took this report to his dentist, who put him under treatment, and he reported in October, 1915, that he was entirely free from pain.

CASE IV.—This patient, a lady 72 years of age, was first seen on April 9, 1915. She had infectious arthritis of both knees, probably from her teeth. She was stout the contour of both knees changed, and she had tenderness below the patella and over the ligament patella. Her symptoms had lasted for a number of years. She had been under treatment for intestinal autointoxication and visceral optosis. An examination at once revealed suspicious looking teeth and a very foul breath. The radiologist reported extensive arthritis in both knees, erosion and deposits of calcareous material, and spurs apparently projecting into the quadriceps tendon; the teeth showed areas of decalcification thought to be due to apical abscesses in both upper central incisors and lateral incisors. Her own dentist referred her to a specialist in the treatment of pyorrhea who gave her decided relief. The ultimate result he had not learned.

CASE V.—This patient was a lady about 45 years of age, whose daughter Dr. Gehring had had under his care for a number of years for spinal disease. He said she called his attention three or four years ago to a most obstinate coccydynia, found the coccyx sensitive, and dilated the sphincter, making pretty sharp movements back and forth of the coccyx with his thumb and finger. She had at that time also pain in her shoulder, and said "she had had a rheumatic throat." His treatment failed to give relief, and as he had found this successful in one or two other cases, he was rather disappointed. On December 7, 1915, she told him that her attention had been called to her teeth last July, when it was found that she had two active abscesses and five cold abscesses at the roots of her teeth. Seven teeth were extracted, and from that time to the date of her report she had had no further rheumatism in either her throat, shoulder or coccyx; in other words, she was in perfect health.

CASE IV.—Dr. Gibney said this patient, a lady 35 years of age, was brought to him June 2, 1915, for what he took to be infectious arthritis of both knees. The first attack occurred twelve years before, which which she made complete recovery. This present attack was of several months' standing; her physician had found an abscess in her right central incisor by means of the x-ray, the necrotic area running back about 2½ inches, apparently connecting with the nasal fossa. At the time of the extraction of the tooth a culture was taken and vaccine used for three months without effect. A culture from the fluid in the knee showed streptococcus, and the same was shown in the alveolar process. It was admitted that the disease had made such rapid progress in the knees that very little could be expected from the removal of the original cause. I did an arthrotomy on both knees, evacuating pus which showed the same culture. The case progressed rather slowly during the summer of 1915, and in September some suspicious points in another tooth were found. She had x-rays again and her tonsils and adenoids were rather prominent. These were removed in November; the suspicious tooth was treated, and under the pituitary extract she was steadily improving. The same culture was found in the adenoids and tonsils. At present she was gaining flesh, free from pain, and the range of motion at the knees was slowly increasing, but her joints were still protected by apparatus. During the summer other joints became involved, such as wrist and elbow, both sides, but all of these are now gradually approaching normal.

CASE VII.—Dr. Gibney said this patient was a gentleman, about 60 years of age, first seen on September 22, 1915. He had a brachial neuralgia which he attributed to cranking his car 5 years before. About a year ago, after most intense suffering throughout the cervical region and over his right shoulder and over the chest walls on right side, he had his jaws x-rayed at the suggestion of a neurologist, but there was nothing found; still some vaccines were made from the alveolar processes and he had about three months' active treatment without result. A list of the names of the distinguished specialists in New York and Boston whom he had seen and the treatment he underwent at the hands of a surgeon in this city upon the suggestion of a Boston surgeon, would make this report

unnecessarily long. At the present time he was still a great sufferer, although he had had the Goldthwait operation done for periostitis of the anterior surface of the scapula. This case was one which he thought bore on the title of the paper of the evening, but the patient had not obtained any relief; in fact, it had never been proven that he had any infection from his teeth, and he himself attributed all of his trouble to the trauma caused by cranking his car.

Dr. Gibney said he wished to impress upon his hearers the necessity of looking for a focus of infection in other parts of the body, as the oral cavity was not the sole location of these foci. The genitourinary men had often accused him of overlooking the foci that were sufficient to cause an osteoarthritis or an arthritis deformans. Again the internists and the gynecologists claimed that the abdominal cavity and the pelvis contained enough foci to infect any part of the body. He concluded by insisting upon examining every part from head to foot when a case could not be distinctly traced to trauma, to syphilis or to malignancy.

The Rhinology.—Dr. CORNELIUS G. COAKLEY believed that Dr. Dana's paper was an epoch-making one in insisting that neuralgic pain usually had some definite local pathological cause. The work of the bacteriologist apparently showed conclusively that the *Streptococcus viridans* was the active infecting agent in the cases reported, and this was a great step in advance. Rhinologists were frequently asked to investigate the upper air passages to determine if possible the source of infection. They began with an investigation of the nose and accessory sinuses. They believed they could rule out as an etiological factor the simple inflammations of the nasal mucous membrane. Collections of pus in the accessory sinuses were frequently found, but they had not been able to connect sinusitis with the so-called rheumatic joint or periosteal infections. There seemed to be no doubt, however, judging from literature, that sinusitis might have caused these infections, but in his own practice he had not seen a single case where he was sure that sinus disease was a cause of the infection. This brought the question down to a consideration of the nasopharynx and the oropharynx as areas from which the infection took place. Both of these regions teemed with all sorts of bacteria. The tonsils usually contained pathogenic organisms, even in a supposedly healthy tonsil, if it was squeezed, and a little milky fluid obtained. This fluid, if cultured in proper media, would be found to contain pathogenic bacteria and almost always the *Streptococcus viridans*, especially if the method advocated by Dr. Hastings was employed. Therefore, Dr. Coakley felt that tonsils that were inflamed were very certain to contain bacteria which might cause pathological processes. On the other hand, any tonsil that was enlarged, red, and manifestly acutely or subacutely inflamed in a person who would frequently give a history of so-called muscular rheumatism, should be looked upon with great suspicion as the focus of infection. Their enucleation was usually followed by very gratifying results. Suspected tonsils should not be examined once, but several times; they might appear normal at the first examination, but evidently diseased in a subsequent examination. The tonsils, however, were not the only foci of infection in the mouth. The isolated lymph nodes and even the general mucous membrane harbored the same microorganisms found in the tonsil, and these organisms might gain entrance into the system, even after the enucleation of the tonsils. This, he thought, might account for some of the failures or recurrent attacks following tonsillectomy.

The Dentistry.—Dr. ARTHUR H. MERRITT said that in consequence of the universality of dental diseases, the mouth was one of the most common sources of secondary infections. One of the most common of these was the dental abscess. These were caused through infection of non-vital teeth and were of two types, the fistulous abscess and the so-called blind abscess. Roentgenographically, they varied all the way from a slight rarefaction to complete loss of bone, often forming a cavity of considerable size within the body of the bone. In their chronic form they were painless and usually unsuspected. Bacteriological examinations showed that a streptococcus was always present—usually the *Streptococcus viridans*. These abscesses were frequently the cause of more or less serious secondary infections, such as those referred to by Dr. Dana. A careful examination should always be made of the mouth in suspected cases, and all non-

vital teeth should be x-rayed. If infection was present, steps should be taken to eliminate it. This did not necessarily mean extraction. To extract a tooth simply because of an infection at the root end was about as intelligent a procedure as to amputate the leg because of a troublesome corn. Pyorrhea alveolaris was another common mouth infection which might seriously affect the general health. This was a disease involving the gums and alveolar process, forming deep pockets and attended in most instances by a discharge of pus. The bacteriology of pyorrhea was an exceedingly complex one, containing many organisms of known pathogenicity, though none of them so far as was known was the specific cause of pyorrhea. They were merely secondary invaders as were amebas. It should be remembered that pyorrhea was a curable disease, though it was only a question of time in every case when it would become incurable. Early treatment was, therefore, most important. The frequency of these chronic localized infections made it necessary to scrutinize the mouth carefully in cases such as those referred to by Dr. Dana to-night, and in every instance see to it that they were eliminated.

Dr. WALTER M. BRICKNER said he wished to speak on this subject from the standpoint of a surgeon who had always been deeply interested in the radiographic diagnosis of bone diseases. Dr. Dana had performed an important service in thus again demonstrating the necessity of seeking a definite cause in all cases of persistent pain. Most of the cases that were treated—or mistreated—as neuritis were not neuritis at all. Just as many of the cases so often regarded as neuritis of the upper extremity were, in fact, instances of subacromial bursitis, so in the lower extremity Dr. Dana had found, radiographically, the cause of persistent pains in lesions of the skeletal tissues. But it would be a great mistake to draw the conclusion from Dr. Dana's cases that the organism to be especially suspected in such instances of periostitis or osteoperiostitis was the *Streptococcus viridans*. This for two sets of reasons: First, the bacteriologic proofs in Dr. Dana's four cases were very incomplete. In one case the chain of evidence seemed very strong if a positive complement-fixation test with the *Streptococcus viridans* was an evidence of systemic infection by that organism. In the other three cases there was no such chain of data. In at least one of them no bacteriological investigation was made. In the only case submitted to operation the bone and periosteum removed were not studied bacteriologically. Second, the periosteum was subject to inflammatory reaction from trauma and from infection by a considerable variety of microorganisms, streptococci, staphylococci, the spirocheta of syphilis, the tubercle bacillus, the typhoid bacillus. While the pictures shown by Dr. Dana did not give the appearance of a typhoid osteoperiostitis, it would have been interesting to learn whether a preceding typhoid infection had been excluded in his cases. In connection with these cases it was important to bear in mind that a negative Wassermann reaction might sometimes be found in cases of bone syphilis. Dr. Brickner had had instances demonstrating this. It must also not be forgotten that an osteoperiostitis, visible radiographically, sometimes betokened a medullary infection that did not show in the x-ray plate. (A cortical bone abscess gave a characteristic roentgen picture, but a medullary abscess might give no such indication of its presence.) Dr. Brickner had had under treatment a young man suffering with severe and persistent pain in the lower thigh. The roentgen rays showed a marked circumscribed osteoperiostitis. Syphilis was excluded by blood and therapeutic tests. The pain proving obstinate to all other therapy, the patient was sent to the hospital, where a surgeon cut down through the thickened periosteum and, finding the bone beneath apparently normal on chiseling, closed the wound. The pain continuing, Dr. Brickner opened the bone into the marrow cavity, evacuating therefrom a circumscribed abscess, which effected immediate relief of pain and a prompt cure.

Dr. BYRON C. DARLING said that the earliest writings he had found were those of Dr. Benjamin Rush of Philadelphia, who said in his book "Medical Inquiries and Observations" the following: "Some time in the month of October, 1801, I attended Miss A. C. with a rheumatism in her hip joint, which yielded for a while to the several remedies for that disease. In the month of November it returned with great violence, accompanied with a severe toothache. Suspecting the rheumatic affection was excited by the pain in the tooth,

which was decayed, I directed it to be extracted. The rheumatism immediately left her hip and she recovered in a few days. She has continued ever since to be free from it." When they considered how often the teeth, when decayed, were exposed to irritation from hot and cold drinks and aliments, from pressure by mastication, and from the cold air, and how intimate the connection of the mouth was with the whole system, he was disposed to believe that they were often unsuspected causes of general, and particularly of nervous diseases. When they added to the list of those diseases the morbid effects of the acrid and putrid matters which were sometimes discharged from carious teeth, or from ulcers in the gums created by them, also the influence which both had in preventing perfect mastication, and the connection of that animal function with good health, he could not help thinking that their success in the treatment of all chronic diseases would be very much promoted by directing their inquiries into the state of the teeth in sick people, and by advising their extracting in every case in which they were decayed. It was not necessary that they should be attended with pain in order to produce disease, for splinters, tumors, and other irritants before mentioned often brought on disease and death when they gave no pain, and were unsuspected as causes of them. This translation of sensation and motion to parts remote from the place where impressions were made appeared in many instances and seemed to depend upon an original law of the animal economy.

Dr. A. JACOBI said that Dr. Coakley's remarks reminded him of what he had been teaching in 1860 and many times since, namely, that in Dr. Coakley's great experience the examination of tonsils which appeared to be diseased and often discharging pus were discharging pus indeed, but in most of the cases he felt he could not connect anything going on in the tonsils with any systemic effects. Dr. Jacobi believed that the tonsils themselves were given too much credit for what was going on and that not enough attention was given to the Waldeyer ring, this ring of lymphoid tissue formed and surrounded by the faucial, lingual and pharyngeal lymph nodes. More attention should be paid to the small crypts about the tonsils than to the enlarged tonsils themselves. This was the point that Dr. Coakley brought out correctly. Dr. Jacobi then reported his personal experience in what he took for and felt for many weeks was sciatic neuritis. His pains were connected with swellings, more or less circumscribed about the sciatic foramen, along the crural nerve of the same right side, about the right gastrocnemius and the right tibia over about one-third of its length. He was not able to find a cause of the illness, which began quite suddenly, but which took weeks to disappear slowly. Tuberculosis or syphilis was not to be considered in the etiology. He was not able to charge any infection known to him with causing it. The swellings were not permanent and he was not inclined to look for osteitis or periostitis as the cause of an ailment like his.

Dr. A. R. STEVENS said he wished to speak of those instances in which the infection came from the genitourinary tract. Cases which had excited greatest interest were those infections which seemed to start from either the prostate or seminal vesicles. He thought there was a popular misconception that these joint or periosteal infections were always due to the Neisser organism. In some acute cases the Neisser infection was present; but in considering the arthritic and periosteal conditions associated with chronic infections of the genitourinary system, it was well to call attention to some convincing work which showed conclusively that six months after the acute Neisser infection had been contracted, a small proportion of cases presented other bacteria in the prostate and seminal vesicles. At the end of the fourth period of six months these secondary invaders could be found in most instances. At the end of three years, as a rule, the gonococcus had entirely disappeared. Consequently, it seemed to him it was a mistake to speak of the gonococcus as the usual cause of any chronic infection originating from the prostate. Urologists had been accustomed to speak of certain pains associated with disease of the prostate or vesicles as so-called "referred" pains. The usual explanation had been that these pains came from areas of the body which received their nerve supply from the same part of the spinal cord which controlled the prostate and vesicles. It seemed to Dr. Stevens that possibly some of these

pains might be due to a periostitis. He thought that in most all of this work, regardless of the origin of infection, the causal relationship between bone or joint infection and some primary focus was based chiefly on clinical observation. Complement fixation tests, and reactions in the skin and in the painful region under consideration following the injection of dead organisms, were suggestive in establishing such a relationship, but not to be depended upon as conclusive. The better such tests were controlled the more valuable they became in specific instances. And, further, the clinical basis for the establishment of an etiological relationship between a focus of infection and a distant lesion or symptom, was, after all, dependent chiefly on the therapeutic test. Such observations had demonstrated that the genital and urinary systems were accountable for a good percentage of cases akin to those under discussion. Accordingly, the prostate and seminal vesicles, as well as the teeth and tonsils, should be included in the routine examination.

Dr. M. L. RHEIN, speaking on the dental side of this question, said he desired to call attention to the fact that he had had over thirty years' experience in recording cases of arthritis, periostitis, and otitis, which could be distinctly traced to periapical infections at the end of roots of teeth. In over fifty cases of this kind a large percentage were entirely cured by the eradication of the infection, and in none of them was there evidence of any pus being present. They were not abscesses in the ordinary acceptance of the term, where a purulent condition was one of the symptoms. There was no external evidence of infection in any of the cases; nothing in the shape of a fistulous tract, nor was there any connection between any of these cases and any pyorrheal symptoms. In every one of the cases the focus of infection was what Dr. Merritt had spoken of as blind abscess. This term "blind abscess" had been in use in dental nomenclature for many years, but was a very bad term, as there was no infection. Of late, it had been much more appropriately designated as "dental granuloma," it being a small tumor, composed largely of granulation tissue and with more or less bacterial colonization, and which almost invariably was found to consist exclusively of *Streptococcus viridans*. These pyogenic microorganisms, while in this condition, unable to produce pus, were constantly manufacturing toxins, which, in turn, were being absorbed in the system. His main object in injecting these few remarks in the discussion was to call attention to the fact that these granulomata were the really dangerous forms of alveolar infections. They were so securely locked in the recesses of the alveolus that the toxins must be entirely taken up by the circulation. Another most important clinical fact was that the virility of these organisms was of so low a type that they very seldom produced the slightest irritation, consequently they did not manifest themselves to the patient. Radiography frequently disclosed these dental granulomata at the ends of roots of teeth that apparently were in the healthiest condition. In fact, he had notes of five or six cases of dental granulomata at the ends of roots of teeth in which no blemish had ever appeared on the surface of the tooth, but in which the pulps were devitalized by some form of traumatism. Dr. Rhein said he felt that nothing more important could be injected into this discussion than the understanding that this was the really dangerous form of dental infection.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 27, 1916.

THE PRESIDENT, DR. FREDERIC E. SONDERN, IN THE CHAIR.

American Medical Association in New York in 1917.—Dr. FLOYD M. CRANDALL moved that the Medical Society of the County of New York extend a cordial invitation to the American Medical Association to hold its annual meeting in New York City in 1917. This was seconded. An amendment was offered and seconded that the delegates be so instructed. It was also amended and seconded that Kings, the Bronx, and Westchester medical societies, together with the New York Academy of Medicine, be requested to cooperate with the Medical Society of the County of New York in this plan. The motion and amendments were carried.

Medical Preparedness.—Dr. YOUNG presented the following resolutions:

Whereas: The Medical Society of the County of New York has expressed itself in favor of preparedness as embodied in the resolution offered by Dr. Nathan S. Jarvis at the Stated Meeting of January 24, 1916, and

Whereas: The military preparation is incomplete without an adequate medical division of the Army, and

Whereas: The proposed increase of the Army does not take into consideration its medical needs, therefore

Be it Resolved: That The Medical Society of the County of New York does hereby express itself as opposed to that clause of the Hay Bill which eliminates the Medical Reserve Corps of the U. S. Army, for the reason that in the opinion of The Medical Society of the County of New York, the Medical Reserve Corp of the U. S. Army is an important factor thereof, and further

Be it Resolved: That in the opinion of The Medical Society of the County of New York the numerical medical strength of the Army should not be less than seven per thousand on a peace footing.

Dr. FOWLER introduced the following:

Whereas: There is under advisement by Congress, legislation to increase the military establishments of these United States, and to remedy our lack of preparedness for war, and

Whereas: In past wars untold sufferings and deaths have been caused by an insufficient number of medical officers, and a lack of adequate means for expanding the Medical Department of the Army in times of emergency, and

Whereas: In spite of these facts, and the indignant protests, and criticisms of the people, the Army Medical Department is to-day even smaller proportionately than in the past, and

Whereas: The medical profession of the United States must be included in any plan for increasing the efficiency of medical preparedness, and for actual service in the field and at home, therefore

Be it Resolved: By The Medical Society of the County of New York that the Hon. Secretary of War and the Hon. Chairman of the Committee on Military Affairs of Senate and House, be and hereby are, petitioned by this Society to urge legislation providing for an adequate medical personnel in the Army, and in the supporting organizations which in time of need, would be called to the colors. The number of medical officers should be such as the Surgeon General of the Army may advise.

Both resolutions were passed.

Intussusception in Infants; Observation Upon a Series of Cases.—Dr. L. MILLER KAHN presented this paper in which he stated that the death rate in intussusception in infants was still unnecessarily high and that his object in reporting this series of cases was to call attention again to the fact that with early diagnosis and early operation practically all of these patients might be saved. The cases tabulated in this series had been admitted to the Lebanon Hospital from January 1, 1910, to March 1, 1916, and were operated on by the surgeons on regular duty. There were in all thirty-eight patients suffering from intussusception, thirty-five of whom came to operation. Of these thirty-eight patients, thirty-three, or 87 per cent., were under one year of age, the youngest being sixteen weeks old. Of the remaining five the ages varied from fourteen months to seven years. Among the infants under one year of age in which the manner of feeding was indicated, 82 per cent. were breast fed. There were nine patients operated on within the first twelve hours of the onset, with one death, a mortality of 11 per cent.; eight patients were operated on between twelve and twenty-four hours after the onset of the initial symptoms, with two deaths, a mortality of 22 per cent.; four came to operation on the second day, between the twenty-fourth and forty-eighth hours, with two deaths, a mortality of 50 per cent. Of the thirteen operated on after forty-eight hours or more had elapsed only three survived, a mortality of 77 per cent. If one excluded two of these patients, one 5½ and one 7 years of age, it would be seen that of the remaining 11 only one recovered, an actual mortality of 91 per cent. Of the 35 patients operated upon there were 20 recoveries and 15 deaths, a total mortality rate of 43 per cent. The nature of the intussusception was stated in 24 instances; 3 were ileocolic; in 18 instances the ileocecal valve acted as the head of the intussusception and carried the appendix with it. The appendix was involved and removed in 9 instances, and in 4 of these it was stated to be gan-

grenous. In 3 instances a double intussusception was present. Resection of the gangrenous bowel was undertaken in 6 instances. No child under one year of age in whom resection of the bowel was done recovered. One resection of bowel in a child five years of age resulted in recovery. A close study of the histories and operative reports of these cases revealed little of importance as to the probable etiological factors. Nothing was observed in this series that would give support to the theory that intussusception resulted from a contraction of circular muscle fibers in the intestines, and that this contracting area, acting as a foreign body, was forced into the nearby non-contracted loop, thus producing the invagination. This explanation of the causation, however, probably accounted for the majority of the cases. After discussing the symptoms of intussusception, the essayist stated that the typical case of intussusception would and actually did present the following picture. A child somewhere between the ages of three months and two years, having previously been in good health, was suddenly seized with violent cramps and gave every evidence of severe suffering. With the onset of pain the child was temporarily blanched, refused nourishment, and vomited. There was perhaps one normal bowel movement, and then the bowels refused to move, only blood-stained mucus or blood being passed. The pain and crying which ushered in the disease might be continuous, but were more likely to have periods of complete remission; the abdomen was soft, and the child seemed comfortable. A small tumor might be made out upon abdominal palpation, or it might be absent. As an early diagnostic sign of intussusception, failure to find a tumor should no longer carry the weight formerly attached to it. Rectal examination would occasionally disclose a mass of bowel coming down from above. Upon withdrawing the examining finger there were usually traces of blood upon it. If no blood had been passed per rectum, the return from the enema showed blood or blood-stained mucus. Gentle bimanual palpation, with one finger in the rectum and the other on the abdomen, might give valuable information. The x-ray had given assistance, and should be employed in dubious cases, if available. Examination under ether was of doubtful value, and should not be employed unless one was prepared to operate immediately. Three cases in the series with positive findings except for the presence of tumor were diagnosed as intussusception, and were relieved after the administration of enemata. There was every reason to believe that the diagnoses were correct, and after the bowels moved with the enemata all the symptoms were relieved. This measure should, with certain limitations, be tried in every case of intussusception, but, after two or three fruitless attempts made in rapid succession, it should be abandoned and operation immediately done. The operation should be performed as rapidly as possible without evisceration. The invaginated loop should be pushed, not pulled, out of the inclosing bowel and all unnecessary steps avoided. The appendix must, when badly bruised, be removed, but even this should not be done unless absolutely necessary. Every precaution should be taken to prevent shock, and the abdominal wound should be closed very securely. Resection might be undertaken if the gut was gangrenous, but had usually proven fatal. Enterostomy might be employed as a last resort. In conclusion, Dr. Kahn said that early diagnosis of intussusception was of the highest importance and should be made by the first physician who saw the case, upon his first visit, if possible. The diagnosis of intussusception having been made, no time should be lost in attempting reduction by enemata, and having failed in this after two or three attempts, the patient should be immediately submitted to operation. The diagnosis of intussusception could safely be made if a typical history was obtained, and blood and mucus found in the stool. The absence of tumor mass should not act as a deterrent to operation. The death rate in intussusception was directly in proportion to the number of hours' delay in submitting the patient to operation.

Dr. SIDNEY V. HAAS said that the only object in bringing such a paper before the society was to impress upon its members the importance of the diagnosis of intussusception in infants. The diagnosis in the majority of cases was not difficult when one was familiar with the conditions. For those unfamiliar with the picture, except as presented in textbooks, the diagnosis was not always so simple. The initial symptoms of sudden pallor, crying and vomiting were often followed in a very short time by an apparently normal

state. The pulse and temperature were normal, the child was ruddy, happy, and playful. It was difficult to believe that a serious condition existed until some hours later, when a condition of shock ensued with an increasing pulse rate, rising temperature, and blood-tinged mucus stool. This period of well-being might last for many hours. It was this quiescent period which doubtless accounted for many of the failures of early diagnosis. Of the physical signs, the most important in his experience besides the tumor mass, which was not always palpable, was the relaxation of the anal sphincter. The differential diagnosis between intussusception and acute ileocolitis with bloody mucus stools might present overwhelming difficulties. Here the relaxed sphincter of intussusception was of the greatest value. The prognosis in these cases depended entirely upon the early diagnosis. A good surgeon could cure practically every case when seen early. Late surgery could do nothing.

Dr. CHARLES HERRMAN said that it was an interesting fact that twice as many cases of intussusception occurred in males as in females. Possibly there was an anatomical reason. The disease was much more common in England and this country than in France and Germany. For example, in his long and large experience Heubner had only seen a dozen cases, whereas many men in this country and in England had reported over fifty cases. The importance of early operation was best illustrated by concrete examples. Northrup some years ago reported two or three cases that had been successfully treated by injections. Later he acknowledged that he was sorry that he had published them, because it encouraged others to try this method and frequently valuable time was lost. A case was reported by Wollin in which a tumor was felt, and injections given. The tumor disappeared and it was supposed that it had been reduced. However, the symptoms continued, and notwithstanding the fact that the mass could no longer be felt, operation was decided on. Invagination with gangrene was found and the child died. The injection might push the tumor toward the diaphragm, so that it was no longer palpable. Behrend reported the case of a boy of eight years who passed a gangrenous portion of the bowel 20 inches in length on the ninth day of the disease. Such remarkable cases stuck in the memory of the student. As a matter of fact such an occurrence was most unusual and it would be almost criminal to wait in the hope that it might occur. Dr. Herrman said he recently saw two cases with other physicians. In both the disease was of more than forty-eight hours' duration, both were immediately sent to the hospital, both were gangrenous, and both died. In both the attending physician had made the diagnosis of probable intussusception, but the parents hesitated about submitting the child to an operation, and there was nothing in the appearance to indicate that it was urgent. It was only when the consultant put it as a matter of life and death that the necessity for immediate operation was recognized. Inspection of the abdomen frequently showed a symmetry or prominent points even when a tumor was not felt. Relaxation of the anal sphincter was often present, especially in the cases that had lasted more than twelve hours. To sum up, the safe rule was to send every suspicious case to the hospital immediately. If the operation was postponed, if gangrene had already set in and if resection was necessary, the little patients almost invariably died.

Dr. EDWARD W. PETERSON said that of about forty cases of intussusception seen by him, twenty-five had been under his personal care. Of this number twenty-four occurred in infants. He wished to present his own results, as they approached rather closely the figures recorded by Dr. Kahn. In his series, one late case died an hour after admission to the hospital, before any operative measures could be instituted; another late case died on the operating table just after the abdomen was opened, in the beginning of an attempt at disinvagination. In eight cases the intussusception was either gangrenous or irreducible or both, necessitating resection or enterostomy—with seven deaths and but one recovery. (The successful case was recorded in detail in the *MEDICAL RECORD*, March 5, 1905.) In fourteen cases, treated by laparotomy and manual reduction of the invagination, there were three deaths and eleven recoveries. The three fatalities were all in late and profoundly toxic cases. Every case seen within forty-eight hours of the onset of symptoms recovered. In a study of intussusception the most striking feature, and, it has been emphasized by Dr. Kahn, was the wide

difference in the mortality in the early and the late operations. In intussusception there was not only obturation obstruction of the bowel, but also strangulation of the blood supply to the obstructed gut. The severity of the early symptoms depended on the degree of strangulation. As had been pointed out by Dr. Kahn, the clinical picture in the intussusception of infants was rather uniform and characteristic; in fact, more so than in any other form of intestinal obstruction. The sudden abdominal pain, with more or less pallor and shock, the pain later becoming intermittent and paroxysmal, vomiting and muco-hemorrhagic stools made up a group of symptoms that was fairly constant. When present but one other symptom was needed to complete the picture, namely, the presence of an abdominal tumor. In twenty-four of the twenty-five cases the tumor could be palpated. Often it was necessary to examine the patient under anesthesia in order to bring out the symptom. Failure to find a tumor, however, in the presence of the other characteristic symptoms, should not bring about any delay in the adoption of radical measures of treatment. The mortality in intussusception was the mortality of delay. It was perhaps unfortunate that hydrostatic pressure and gas or air inflation succeeded in reducing a limited number of invaginations, for such measures were often persisted in until the time for a successful operation had passed. The limitations of aerohydrostatic measures could not be emphasized too strongly. Early laparotomy with manual reduction of the invagination was the simplest, the safest, and the only certain method of treating intussusception.

Dr. LEON T. LE WALD showed some lantern slides in order to show the value of the x-ray in the diagnosis of intussusception in infants.

Quiet Hip Disease, a New Clinical Entity.—Dr. HENRY LING TAYLOR presented this communication. He said that about five years ago it was noticed that certain hip cases in children ran a very mild course and without the usual complications and terminal disabilities of tuberculous hip disease. The trouble usually began from the fifth to the tenth year with a moderate limp, often with little or no pain, and was associated with characteristic symptoms. The onset was usually very insidious, an inconspicuous limp coming on gradually without any known cause. Mobility at the hip was often only slightly restricted at first and spasm was absent; but later, lateral motion and rotation in flexion, especially abduction and internal rotation, might be much limited, and there might be some spasm on attempting to force the motion. Dr. Taylor presented several patients to illustrate these points. They were first asked to walk and without apparent restrictions; then when placed on a table the restrictions were pointed out, none of them, however, very marked. The plane of flexion was usually deviated outward, but flexion to nearly 90° and often beyond was preserved. The mobility resembled that of an early period of osteoarthritis in the adult. Pain might be present at some stage of the affection, usually after overactivity, but this was rarely an important or conspicuous symptom. In some cases there was no shortening of the affected limb, but in the majority there was a shortening of one-quarter to one-half an inch. In most of the cases there was moderate atrophy of the limb. These children were, as a rule, in excellent health; they never had toxemia, abscess, enlarged glands, fixed deformity, ankylosis, serious suffering, or disability. The symptoms had some resemblance to those of coxa vara and to some cases of slipped epiphysis and hemorrhagic osteomyelitis, or cysts of the neck of the femur; but they were easily distinguished by the Röntgenogram. The affection lasted from one to three years and terminated in recovery with a remodeled joint. The tendency was to over-treatment on an erroneous diagnosis of tuberculosis of the hip. Most of the cases received little or no mechanical treatment and did well. Traction, braces, operations, and long periods of recumbency were unnecessary, if not detrimental. This affection was a clinical entity which it was important to separate from tuberculosis, syphilis, coxa vara, and some of the rarer hip affections. It was evidently not very rare. Quiet hip disease in children was unquestionably one source of the affection known as osteoarthritis of the hip in adults. Some of the mild and obscure hip cases in children, where the diagnosis had been uncertain, were cleared up and shown to be quiet hip disease after careful raving. In order to avoid error, it was necessary to ray all hip-joint and borderline cases. In conclusion Dr. Taylor said that quiet hip disease, osteochondritis of the

hip, or Perthes' disease, was a distinct morbid entity which should not be confounded with other hip affections. It had characteristic symptoms, Röntgenogram, course, and termination. It was benign and not very rare. The treatment was simple and the prognosis good. It was a dysostosis of unknown causation. It was one cause of osteoarthritis of the hip in adults.

Dr. PERCY W. ROBERTS said that the subject of quiet hip disease was more important to the general practitioner than was generally realized. Heretofore nearly all chronic lesions of the hip were classified as of tuberculous origin. Many of them might be due to syphilis, but they could not be cleared up until they had been placed under treatment. It was due largely to the efforts of Dr. Taylor that enlightenment resulted in the study of this condition. Fortunately the diagnosis was comparatively easy. The clinical picture was one that was not apt to be confounded with anything else. Dr. Roberts said he wished to emphasize the fact that they were dealing with a lesion that had been overlooked in years gone by.

Dr. P. WILLIAM NATHAN said that they knew that tuberculosis of the hip was a particularly difficult disease to treat, and even the results of the best management of the joint were not always satisfactory. For this reason when they examined a child with this condition of the hip, usually a bad prognosis was made. However, if they took a child with such a condition and took him off his feet for a long time and compelled him to give up the pleasures of childhood and wear braces or spica, what would be the result? In recent years they had discovered a number of instances where the condition of the quiet hip closely resembled tuberculous disease; many of these cases were of mild form and required braces or spica and the prognosis was good. Dr. Nathan thought that the general practitioner should appreciate the efforts of Dr. Taylor, even more so than the specialist.

Dr. WILLIAM FRIEDER said that most of these cases were treated as tuberculous disease of the hip and he reported the following instances:

CASE I.—A boy of eight years was seen in April, 1912. He fell one month before seen. He complained of no pain. Then there appeared a gradual limitation of motion in both hips. Now there was no limitation of motion in either hip. The x-ray showed a flattening of the head of the right femur, but the x-ray of the left hip was negative. In July, 1913, a short spica was used. Following this there was no pain, shortening or limitation of motion. The Wassermann and the tuberculin tests were negative. In October, 1913, there was an increase of the limp and of progressive changes in both hips. There was no pain or spasm.

CASE II.—The patient was a girl, aged ten, who complained of trouble in her right hip. There was a gradual onset of limp. There was no trauma. Flexion was free, rotation and abduction were markedly limited. There was no shortening. The x-ray showed typical changes.

CASE III.—This was a boy, aged six, who had an onset of symptoms eighteen months ago, of lameness, with occasional pain in the groin. At that time all hip motions were free and the x-ray findings were negative. The limp persisted and a short spica was applied after six weeks. Six months later the x-ray showed some flattening of the head and roughening along the epiphyseal line. All the motions were slightly restricted. In March, 1915, the length of the legs were equal and there was some limitation of the lateral motion and flexion. There was no spasm. The Wassermann test was negative. In April, 1915, the x-ray showed a flattening of the head, a thickening of the neck, and a slight coxa vara.

Dr. TAYLOR said that the diagnosis of this condition of the hip was not always easy and in order to make sure of the diagnosis the x-ray should be employed.

A Serological Study of Presenile Gangrene (Thromboangitis Obliterans) with Reference to the Possibility of Typhus Fever Being an Etiological Factor. A Preliminary Report.—Dr. CHARLES GOODMAN read this paper. He said that probably no other disease had recently aroused more interest on the part of the clinician, surgeon, and pathologist than the condition generally known as presenile gangrene of the extremities of thromboangitis obliterans (Buerger). The causative factor had up to the present time not been discovered. The first case of this disease came under Dr. Goodman's observation some twenty years ago when he was an interne at the Mount Sinai Hospital. Since that time he had had the opportunity of studying over two hun-

dred cases. A review of the literature showed that presenile gangrene of the extremities was more or less common in almost every country, but was more prevalent in those countries where typhus was epidemic, as in Russia, Austria, Japan, Bulgaria, Turkey, etc. The number of cases in any country was almost in direct proportion to the frequency of the epidemic of typhus fever. The majority of the cases seen in this country had been among the poor Jewish immigrants from Russia and Galicia, so that some of the writers had believed the condition to be one peculiar to the Jewish race. This was a misconception, as was evidenced by the fact that the disease was seen in countries where typhus fever was epidemic irrespective of the ethnic condition of the population. For a number of years Dr. Goodman was inclined to share the prevailing opinion that cigarette smoking entered largely into the etiology of the disease; but there were thousands in this country and elsewhere who were inveterate smokers and did not develop this disease. Syphilis as an etiological factor could be excluded. On the occasion of a visit to Breslau several years ago Dr. Goodman said he had been informed by two of the assistants of Prof. Kuettner that gangrene of the extremities had been found to be quite frequent while they were doing medical service in the Bulgarian campaign. It therefore struck him that, in view of the great frequency of typhus fever and cholera in the Bulgarian camps, there might be a causal relationship between these infections and the frequent occurrence of gangrene. In a recent conversation with Prof. Hans Zinsser the latter informed him that during his recent visit to Servia he had observed a considerable number of cases of gangrene of the extremities. A careful research of the literature revealed the fact that other authors had suspected the infectious origin of thromboangitis obliterans. The specific microorganism of typhus fever having at last been isolated by Plotz, Olitsky, and Baehr, Dr. Goodman considered it advisable to have serological studies made. A perusal of the results showed that, while definite conclusions could not be drawn, they indicated the importance of carrying on further studies.

Serological Studies.—Dr. EUGENE P. BERNSTEIN said that Dr. Goodman had sent to him sera from twenty-one cases which were clinically diagnosed as cases of thromboangitis obliterans. The agglutination reactions and complement fixation tests were made according to the methods described by Dr. Olitsky. In each a negative and positive control were made. In eighteen of these cases the serological reactions were negative, thirteen being studied once and five cases being studied twice. The three other cases gave quite marked reactions. In one case there was almost complete agglutination up to 1-200, and in two of the cases incomplete agglutination up to dilution of 1-400. As a result of the studies made by Drs. Plotz, Olitsky, and Baehr, they concluded that agglutination reactions up to dilutions of 1-50 were not specific. In a study of ninety-eight control cases a strong complement fixation test was not found in any one of them. Complement fixation tests were, however, found positive in a certain number of people who had been in contact with typhus fever. It was possible that the positive reactions found in three cases of thromboangitis obliterans out of a total of twenty-one might have been due to the fact that these people had been contacts or might have had typhus fever. It was important to remember that patients with typhus fever could lose their serological reactions even in as short a period as five months following the termination of the disease.

Industrial Medical Supervision.—Arthur B. Emmons, 2nd, gives the results of his experience as surgeon to a large confectionery employing eight hundred to a thousand men and women, largely unskilled labor. In his work he had the assistance of a full-time trained nurse. He says that this inspection and supervision accomplishes the following advantages: It gives to the employer increased good will, steadier, quicker, and more contented employees; greater cleanliness of shop and produce and sufficiently improved conditions to make the outlay entirely justified. It offers to the doctor and nurse opportunity to be of distinct service to their patients, and to assure cleanliness and freedom from disease in the food manufactured. This is no small service to the employees, the directors, and the consuming public. The writer asks whether, when the public is aware of these safeguards, other employers can afford to be without such safety and advantages. —*Boston Medical and Surgical Journal.*

Books Received.

The MEDICAL RECORD is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading; but this is with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.

THE PRACTITIONER'S DICTIONARY. By GEORGE M. GOULD, A.M., M.D. Revised by R. J. E. Scott, M.A., B.C.L., M.D. Published by P. Blakiston's Son & Company, Philadelphia. Contains 962 pages. Price, cloth, \$2.75; leather, thumb index, \$4.50.

THE BASIS OF SYMPTOMS. By DR. LUDOLPH KREHL and ARTHUR FREDERIC BEIFELD, Ph.B., M.D. Published by J. B. Lippincott Company, Philadelphia and London. Contains 520 pages. Price, \$5.

PULMONARY TUBERCULOSIS. By MAURICE FISHBERG, M.D. Published by Lea & Febiger, Philadelphia and New York. Contains 639 pages with illustrations.

STUDIES IN ETHICS FOR NURSES. By CHARLOTTE A. AIKENS. Published by W. B. Saunders Company, Philadelphia and London. Contains 320 pages. Price, \$1.75.

THE JOHNS HOPKINS HOSPITAL REPORTS. Published by Johns Hopkins Press, Maryland. Contains 586 pages with illustrations.

SECOND ANNUAL REPORT OF THE TRUSTEES OF THE NORFOLK STATE HOSPITAL, FOR THE YEAR ENDING NOVEMBER 30, 1915. Printed by Wright & Potter Printing Company, Boston.

SEVENTH ANNUAL REPORT OF THE COMMISSIONERS OF THE STATE RESERVATION AT SARATOGA SPRINGS. Printed by J. B. Lyon Company, Albany.

PROCEEDINGS OF THE MEDICAL ASSOCIATION OF THE ISTHMIAN CANAL ZONE, FOR THE HALF YEAR—OCTOBER, 1914 TO MARCH, 1915. Printed by the Canal Press.

CLEFT PALATE AND HARE LIP. By SIR W. ARBUTHNOT LANE, BART., M.S., F.R.C.S. Published by the Chicago Medical Book Company. Contains 102 pages, with illustrations. Price, \$4.

BACTERIA AND PROTOZOA. By HERBERT FOX, M.D. Published by Lea & Febiger, Philadelphia and New York.

MAN—AN ADAPTIVE MECHANISM. By GEO. W. CRILE, F.A.C.S. Published by The Macmillan Company, New York. Contains 387 pages. Price, \$2.50.

OPHTHALMOLOGIE DU MÉDECIN PRATICIEN. By DR. ALBERT TERSON. Published by Masson et Cie, Paris. Contains 480 pages with illustrations. Price, 12 fr.

SURGICAL ANÆSTHESIA. By H. BELLAMY GARDNER, M.R.C.S., L.R.C.P. Published by William Wood & Company, New York City. Contains 220 pages, with illustrations. Price, \$2.25.

BACK INJURIES AND THEIR SIGNIFICANCE. By ARCHIBALD MCKENDRICK, F.R.C.S.E., etc. Published by William Wood & Company, New York City. Contains 173 pages, with illustrations. Price, \$1.25.

THE MEDICAL CLINICS OF CHICAGO. Published by W. B. Saunders Company, Philadelphia and London.

ANNUAL REPORT OF THE HEALTH OFFICER OF THE PORT OF NEW YORK. Printed by J. B. Lyon Company, Albany.

TRANSACTIONS OF THE AMERICAN CLIMATOLOGICAL AND CLINICAL ASSOCIATION. Guy Hinsdale, M.D., Editor.

THE AMERICAN YEAR BOOK. Edited and published by D. Appleton and Company. 862 pages.

Vital Statistics for 1914.—A preliminary announcement from the Bureau of the Census with reference to mortality in 1914, puts the total number of deaths in the registration area, which contains about two-thirds of the entire population of the United States, at 898,059, more than 30 per cent. of which were due to three causes—heart diseases, tuberculosis, and pneumonia—and more than 60 per cent. to eleven causes—the three just named, Bright's disease and nephritis, cancer, diarrhea and enteritis, apoplexy, arterial diseases, diphtheria, diabetes, and typhoid fever.

The deaths from heart diseases numbered 99,534, or 150.8 per 100,000 of population; this is a marked increase over 1900, when the rate was only 123.1 per 100,000.

Tuberculosis caused 96,903 deaths, of which 84,366 were due to the pulmonary disease. This gives a death rate per 100,000 of 146.8, an encouraging decline from the rate of 200.7, which was recorded in 1904.

Pneumonia caused 83,804 deaths, or 127 per 100,000, the lowest rate on record for this disease.

Bright's disease and nephritis were responsible for 67,545 deaths, giving a rate per 100,000 of 102.4; the mortality from these two causes increased from 89 per 100,000 in 1900 to 103.4 in 1905, since which year it has fluctuated somewhat.

Cancer and other malignant tumors caused 52,420 deaths in 1914, nearly 38 per cent. resulting from cancers of the stomach and liver. The death rate from cancer has risen from 63 per 100,000 in 1900 to 79.4 in 1914. The increase has been almost continuous, but it is possible that a part at least is due to more accurate diagnoses and greater care in the making of reports.

Diarrhea and enteritis caused 52,407 deaths, or 79.4 per 100,000, the rate in 1913 having been 90.2, and that in 1900 133.2. Nearly five-tenths of the total number of deaths charged to these causes in 1914 were of infants under two years of age.

Apoplexy was the cause of 51,272 deaths, a rate of 77.7 per 100,000; arterial disease of various kinds, of 15,044 deaths, a rate of 22.8 per 100,000; diphtheria and croup, of 11,786, a rate of 17.9; and diabetes, of 10,666 deaths, a rate of 16.2 per 100,000. The rate from the last-named disease has risen almost continuously since 1900, when it was 9.7 per 100,000. The mortality rate from typhoid fever, on the contrary, has fallen since 1900, when it was 35.9, to 15.4 in 1914, the total number of deaths in the latter year being 10,185. The principal epidemic diseases of children—whooping cough, measles, and scarlet fever—together caused 15,617 deaths, or 23.7 per 100,000, the rates for the three separately being 10.3, 6.8, and 6.6 respectively.

Mental Hygiene.—With the cooperation of a number of physicians and educators, the Committee on Mental Hygiene of the State Charities Aid Association will shortly begin a campaign of education, through the medium of lectures, for the prevention of insanity. The committee is endeavoring to reduce the alarming amount of mental impairment in the State by making careful public statements as to the nature, cause and prevention of diseases of the mind and by securing more effective treatment in the home as well as in hospitals and dispensaries, for persons in the early stages of mental disease.

THE TREATMENT OF PYORRHEA ALVEOLARIS AND ITS SECONDARY SYSTEMIC INFECTIONS BY DEEP MUSCULAR INJECTIONS OF MERCURY.*

BY BARTON LINSIE WRIGHT, M.D.

SURGEON, UNITED STATES NAVY

HASSELTINE¹ of the United States Public Health Service has described dentistry as "a highly specialized branch of surgery." The brilliant work of Brophy and of the numerous other oral surgeons bearing dental degrees, have brought you honors second to none in the field of surgery. Your skilful restoration of the functions of the jaws (teeth), through prosthetic procedure, is an exhibition of surgical skill of no mean order.

The present great war in Europe, presenting as it has, a high percentage of face wounds, most of which have involved the oral cavity, has demonstrated beyond question that the dental surgeon is indispensable in military surgery, and I believe, and venture to assert, that no other surgical specialty is so closely identified with internal medicine as is dentistry. Granting its brilliant surgical achievements, and having the greatest admiration for the men who have created the ever-widening scope of oral surgery, I am confident that through pyorrhea alveolaris, root abscess, and dental caries, all of which are primarily causative factors in systemic infections, you will come into your fullest honors, and confer upon humanity, the greatest benefits; becoming as indispensable in certain lines of internal medicine as you have already demonstrated yourselves to be in certain lines of surgery.

Pyorrhea is one of the most frequent and widespread infections found in human beings, its local devastations are sufficient in themselves to warrant every effort upon our part to effect a cure, and when we consider it in relation to the various systemic infections for which it is so frequently primarily responsible, many of which are serious and some fatal, our responsibility to our patients is at once apparent.

No other local focus of infection is so fraught with danger to the patient as is the disease in question, for the bacterial flora found in the pyorrheal pockets and pus is at once numerous and varied. Therefore any specific infectious disease, acute or chronic, may be secondary to it, or focal infections of any organ or tissue may be caused by it, making pyorrhea not only of the greatest importance to the internist, but to the eye specialist, the throat, nose,

*Read before the Harvard Odontological Society, at its annual meeting, Boston, Massachusetts, February 26, 1916, and The North Eastern Massachusetts Dental Society at its annual meeting, Haverhill, Massachusetts, March 1, 1916.

and ear specialist, the gastroenterologist, the genitourinary specialist, the gynecologist, the obstetrician, the specialist of the nervous system, and the general surgeon as well.

Of all the secondary systemic infections found associated with pyorrhea, the most frequently seen is arthritis (so called rheumatism) in its various forms; this disease so productive of intense suffering, is probably, next to tuberculosis, the most disabling, and therefore from an economic standpoint, one of the most important diseases we have to combat. Thousands of these poor sufferers are completely disabled and rendered unproductive annually in the United States alone, representing an economic loss of many million dollars to the country.

Therefore it must be apparent that the cure of pyorrhea, long regarded by the medical and dental professions as more or less incurable, is of most vital importance, not only to prevent its local ravages, but more particularly as a prophylactic measure against systemic invasion, or where this systemic invasion has already taken place, to remove the source, thereby making the permanent cure of the systemic infection a possibility.

The treatment suggested and practised by me in cooperation with my dental colleague, Doctor Paul G. White, U. S. Navy, is based on the theory that: For every vegetable parasite mercury is the chemical affinity, and when properly injected into the infected host will cure the specific disease. This is represented by a chemical formula as follows: (Vegetable antigen + Hg) + antibody + complement = complement fixation (immediate cure).

I now believe that mercury has a dual parasitotropic action:

First, primary or direct, in which the Hg by affinity unites with the organism, and without antibody, binds complement. Represented by formula as follows: Vegetable antigen + Hg + complement = complement fixation (immediate cure). Total destruction of all the infecting parasites or of their virulency with immediate cure takes place. I am led to believe that this action is limited to the first few days after the onset of the acute infectious diseases, the period of time during which it will take place seeming to differ in each disease; in some it will be found to extend to the sixth day, in others probably only during the first or possibly the second day. This is due, I believe, to changes in the organisms acquired by the prolongation of their existence in their new environment, by which they gradually lose most if not all of their affinity for mercury. I have never seen this action take place in a subacute or chronic infection.

Second, secondary or indirect, for the reasons noted above, the affinity of the organisms for Hg having been partially or completely nullified, instead of uniting with them, Hg stimulates the rapid production of specific antibody.

This secondary action takes place in two stages and may be represented by chemical formulæ as follows: *First stage:* Vegetable antigen + Hg = stimulated specific antibody production. *Second stage:* Vegetable antigen + antibody + complement = complement fixation (rapid cure). These reactions take place in the last stages of acute, and throughout the course of subacute and chronic infections, producing as a rule marked beneficial, with rapid but not immediate curative effects.

It is probable that both the direct and indirect actions of mercury in these infections occur in every case injected; under certain conditions one or the other predominating, the other taking a subsidiary part in the cure. It is the secondary or indirect action of mercury which manifests itself in the chemotherapy of pyorrhea.

The cure of this disease, with its multiplicity of possible etiological organisms, embracing as it does all of the vegetable parasites, and one, a protozoan, the *Endamæba buccalis*, with the systemic administration of mercuric succinimide, is an argument that must prove convincing, when considering my theory in relation to the treatment of many systemic diseases and local foci of infection.

The ultra conservatism of the medical profession to any new idea in medicine, no matter by whom advanced, is generally well recognized; in some instances this is of distinct advantage to humanity, as evidenced by the fiasco of our late visitor with his living tubercle bacterin, derived from the turtle.

On the other hand the opposition to the introduction of von Behring's diphtheria antitoxin, and more recently to Ehrlich's theory and the administration of salvarsan, was equally pronounced, and had it been successful, would have deprived humanity of two of its greatest blessings.

The attitude of the profession to my theory is (1) this one of conservatism, enhanced no doubt, by their inability from long years of habit, to disassociate mercury from the treatment and diagnosis of syphilis. Up to the time of the introduction of the Wassermann test as a diagnostic agent for syphilis, the therapeutic test was frequently applied to patients who presented neither a history nor any of the symptoms of this disease, but if they improved under mercury were considered to be syphilitic. In this way many a patient was branded a syphilitic who was entirely innocent of the disease, as is well demonstrated by the cures obtained through the administration of mercury in various diseases by Souligoux and Giru who reported in the *Archives de Chirurgie* of November 25, 1912, 144 consecutive cases of puerperal septicemia treated by deep muscular injections of mercuric cyanide, gr. 1/6 daily, with but three deaths.

Krohl² states that benzoate of mercury administered by deep muscular injections in proper doses is not only a cure for all streptococcic infections but will prevent them.

Bacelli³ treats acute rheumatic fever by intravenous injections of mercuric chloride with brilliant results, in which he is corroborated by Carlo,⁴ Maragliano,⁵ Singer,⁶ and Martone.⁷

Edlavitch⁸ reports the successful treatment of a case of spastic paraplegia (non-syphilitic) by intraspinal injections of mercurialized serum.

Barlow⁹ reports a case of tertian malaria treated by intravenous injections of mercuric chloride with most brilliant results.

For my own results along other lines I refer you to my former papers, the latest of which appeared

in the MEDICAL RECORD under date of July 11, 1914.

(2) They fail to grasp the fact demonstrated by themselves, that a single therapeutic agent can be parasitotropic for an entire group of organisms, such as the vegetable parasites, wherein each specific organism is supposed to invariably produce a specific disease, forgetting that the chemical constituents of each of these organisms are almost identical, also failing to note or to remember that transmutation of these organisms may take place with changed conditions of environment, streptococci becoming pneumococci, which when injected into an animal produce typical pneumonia; anthrax bacilli becoming cocci, which when injected into an animal produce a disease entirely unlike anthrax; the hay bacilli becoming tubercle bacilli, which when injected produce typical tuberculosis; the tubercle bacilli becoming cocci, all this having been satisfactorily demonstrated by Rosenow, the Pasteur Institute of Paris, and Maher⁸ respectively. The possibility at least of this entire group of organisms being but one organism, having been thus demonstrated, changing form and specific characteristics, but not chemical composition, which may produce one disease to-day and another to-morrow, depending upon environment, is but another convincing argument in favor of the correctness of my theory.

Such is the inconsistency of human nature that what the profession deems impossible in relation to this group of vegetable parasites, they freely grant to that group comprising the pathogenic animal microorganisms; every up-to-date text book on medicine states that arsenic (salvarsan, neo-salvarsan, or atoxyl) is a specific cure for syphilis, yaws, relapsing fever, sleeping sickness, and others.

Having formed no habit for, or developed any prejudice in relation to salvarsan, the profession at first used it indiscriminately in the treatment of diseases of all kinds, quickly discovering that it had no curative value in diseases of vegetable parasitic origin, but that it is a specific cure for the diseases of microorganismal animal parasitic origin.

This renders the argument, "that it is impossible for a single therapeutic agent to be parasitotropic for all the organisms comprising a group" most absurd, and is a third convincing argument in favor of the correctness of my theory.

The organisms most frequently found associated with pyorrhea are the streptococcus-pneumococcus group, several varieties of spirochetes, and a fusiform bacillus, all of which are vegetable parasites; these and others of this group, less frequently found, are the organisms which by entering the blood stream and lymph channels produce the various secondary systemic infections, as is particularly well demonstrated by Hartzell and Henrici⁹ in their paper "The Dental Path: Its Importance as an Avenue to Infection."

Since the first publication of Smith and Barrett relating to the *Endamæba buccalis*, this organism has received considerable attention from both the medical and dental professions; it is present in almost every case of pyorrhea, whether as a causative factor or as a beneficial agent is yet to be determined; it has never been found in the blood stream or in tissues or parts of the body showing evidence of a secondary systemic infection, and can therefore be ignored when considering these.

At the present time I believe that the consensus of opinion is that the amebicide emetine is of more or less benefit in pyorrhea but not a cure; even this, however, is a distinct advance in the treatment of

this disease, for which Drs. Smith and Barrett should be duly credited.

We began the treatment of this disease with mercuric succinimide May 4, 1914, before the publication of Smith and Barrett's original paper, and our results were so brilliant that we did not feel justified in using emetine, believing that, even should the *Endamæba buccalis* prove to be the specific organism of pyorrhea, these results would demonstrate that in mercuric succinimide we had an amebicide far superior to emetine, in addition to its being a parasitotropic agent of the greatest possible value in relation to the vegetable parasites. Dr. Weston A. Price," President of the Research Institute of the National Dental Association, who has had considerable experience with emetine in the treatment of pyorrhea, and a shorter experience with mercuric succinimide states: "We believe it (mercuric succinimide) to be superior to emetine in a majority of cases." Riethmüller has stated, "as a matter of fact, after one administration of succinimide of mercury, it is absolutely impossible to demonstrate *Endamæba buccalis* in pyorrheal pockets."

At the Navy Yard, Portsmouth, N. H., we have completed the treatment of seventy-five cases of pyorrhea; among these were noted the following secondary systemic infections: four cases of acute infectious arthritis—so-called acute rheumatic fever, twenty-one cases of chronic infectious arthritis—so-called chronic articular rheumatism, one case of chronic bilateral facial neuralgia, three cases of chronic unilateral facial neuralgia, one of chronic laryngitis, one of chronic otitis media, six cases of chronic lumbar myositis (lumbago), three cases of myositis of other muscles, and locally associated with the pyorrhea, four cases of perialveolar abscess; that is to say, exclusive of the local abscess cases, forty-one (54 per cent. of the total number of cases treated) presented secondary systemic infections.

In every case the pyorrhea was cured, and by this I mean that, in addition to the absolute disappearance of pus, the gums became normally pink, hard, and firm, pockets were obliterated and loose teeth firmly fixed, nor have we been able to find a single case in which the disease has recurred.

In addition to these brilliant results, all the cases of secondary systemic infection were also cured in remarkably short periods of time.

In corroboration of this, A. A. Dental Surgeon G. H. Reed, U. S. Navy, at the Boston Navy Yard, will shortly publish a paper in which he reports fifty consecutive cases of pyorrhea treated by this method with practically 100 per cent. of cures. Dr. C. S. Copeland¹² of Rochester, N. H., has published eleven consecutive cases, all of which were cured, and it is interesting to note that six of these cases presented secondary systemic infections, or 54 per cent., it being the same percentage as in our own series; these were also either cured or markedly improved at the time of writing.

Dr. E. C. Blaisdell of Portsmouth, N. H., in co-operation with Dr. Samuel T. Ladd, and Dr. J. H. Neal, report twenty cases treated and cured.

In one case of Dr. Ladd's, a young man, 22 years of age; was first seen on July 4, 1915. He gave a history of pulmonary tuberculosis of some three years' standing, during which time he had been treated in two Eastern sanatoria and had just returned from southern California to die; he presented on that date all the symptoms of advanced tuberculosis, temperature 102.6°, pulse 118, respira-

tions 30. Apex and lower right lobe and upper left lobe were very widely involved with extensive pleurisy, severe night sweats, characteristic sputum, weighing 102 pounds. He also had pyorrhea. He has now had three series of injections of six doses each, ranging from gr. 5/5 to gr. 9/5, and presents the following condition: cough and sputum have practically disappeared; sputum negative for tubercle bacilli; no night sweats since third injection; lungs are dry and lesions have most markedly improved; weight 146 pounds; pyorrhea cured. He has returned to work, but is still under observation and treatment. Two others had chronic iritis for years, with frequent exacerbations; they both had been treated by several excellent eye specialists, with only temporary improvement; with mercury and local treatment the pyorrhea and iritis in both cases have entirely disappeared. One severe case of ten years' standing had a severe chronic gastritis and chronic appendicitis. His pyorrhea was cured by three injections, the last given April 22, 1915, since which time he has been free from gastric and appendix symptoms. Three others had severe chronic arthritis which was also cured.

Treatment.—Besides the bacterial infection, there is a second factor that requires every consideration, viz., that in a very large majority of cases calcareous deposits occur to a greater or lesser degree along the roots and necks of the teeth, which, acting as foreign bodies, are a constant source of irritation. It is, therefore, obvious that in order to cure this disease in a large majority of cases two courses of treatment must be pursued at the same time: (1) The infecting organism or organisms must be attacked by the use of some parasitotropic agent, and (2) during the administration of this agent, surgical interference must be resorted to locally, all calcareous deposits and tartar wherever found being removed, and the toilet of the oral cavity being made as perfect as possible.

The multiplicity of the organisms productive of this infection makes it necessary to select for systemic administration an agent parasitotropic to them all. That mercury in proper doses and properly administered has this qualification when the vegetable parasites are in question, I have repeatedly demonstrated.

If it is found that the *Endamæba buccalis* is the primary causative factor in pyorrhea, our results and the observations of Price and Riethmüller would show conclusively that mercury is also parasitotropic for this particular protozoan at least.

In this disease, in the male patient, a deep muscular injection of mercuric succinimide, gr. 1 (65 mgm.), should be administered every seventh day, until the discharge of pus has entirely disappeared, and the gums have regained their normal condition and appearance. In female patients the dose should be from gr. 1/5 (13 mgm.) to gr. 2/5 (26 mgm.) less than that administered to males. Mercurialism of any marked degree should be met with smaller doses at succeeding injections, or, if the symptoms are severe, the mercury is discontinued until they have disappeared.

Technique.—The syringe used is all glass, and holding forty minims. The needles used are No. 26, intramuscular, for the above syringe.

Syringe and needle are sterilized before using. The solutions are so made that gr. 1/5 of mercuric succinimide is dissolved in four minims of hot, sterile distilled water.

The site of injection is the buttock, using alter-

nating sides for succeeding injections. The skin is sterilized with tincture of iodine. The method of inserting the needle is as follows: The needle butt is held between the thumb and third finger with the index finger over the butt, the shaft of the needle to be perpendicular to the skin surface, the point about three inches distant from it. With a quick, forceful, downward thrust, the needle is driven deeply into the substance of the gluteal muscles, from point to butt. Then into the syringe as many minims of the sterile mercuric solution as represent the desired dose are drawn; if it is to be gr. 5/5, minims XX will be required. Then the syringe tip is inserted into the socket of the needle, and the injection is made slowly. The needle is withdrawn, and tincture of iodine is applied to the point of injection. The injections are to be repeated every seventh day.

Local Treatment.—The local treatment as administered by Dr. P. G. White, embraces the following steps: Careful expression of the pus from the pockets, thorough removal of calcareous deposits and tartar wherever found; extraction of hopeless teeth and roots, polishing of the tooth structure, followed by applying to the margin of the gums equal parts of tincture of iodine, tincture of aconite, and chloroform, continued every other day. This latter procedure may be and has been omitted in many of our cases without any appreciable difference in the time required to effect a cure, but we consider it a valuable adjunct to the local curettage and systemic treatment.

Number of Injections.—The longest period of time required to effect a cure was forty-one days, the shortest four days; average seventeen days. The greatest number of injections required to cure the primary infection in any one case was seven, the smallest number one; average 2.9. The diagnosis in each case was based upon classical symptoms and conditions; pus was present in every case, the presence of slight pathological changes in the gum tissue, or of any particular organism, not being considered as diagnostic.

The following case well illustrates many of the points I have endeavored to impress upon you:

CASE: F—J. F., Chief Master-at-Arms, U. S. Navy, age 48 10/12 years, married, wife perfectly healthy, never conceived. Admitted to the U. S. Naval Hospital, Portsmouth, N. H., from the U. S. S. *Leonidas*, October 1, 1914, as with chronic articular rheumatism, all joints involved, moderate temperature, suffering intensely. Treatment: bed, salicylates, bicarbonate of soda, various local applications. Wassermann negative. He remained under treatment until January 19, 1915, during this time three additional Wassermann tests were negative.

There being no change in his condition, on the latter date he was transferred to the U. S. Army and Navy General Hospital, Hot Springs, Arkansas.

This institution is devoted solely to the treatment of the various forms of so called rheumatism, excepting syphilitic, patients with this disease not being accepted. Upon admission, he was given a fifth Wassermann test, which was also negative. He remained under the special treatment given in this hospital for about four months, when he was discharged improved, all joints being normal, excepting those of both feet. Upon his arrival on board the Receiving Ship at the Navy Yard, Norfolk, Va., May 12, 1915, he was immediately transferred to the Naval Hospital at that place for further treatment. His home being in Portsmouth, N. H., he requested transfer to the Navy Yard at that place, and reported on board of the U. S. S. *Southery* June 2, 1915.

Fearing that if he presented himself to the medical officer, he would again be sent to hospital and probably surveyed and discharged from the service for physical disability, he explained to his commanding officer his condition, who kindly gave him very light

duty in the enlisted men's reading room, which did not require him to be on his feet.

He continued in the performance of his duty until July 27, 1915, when he reported to me at the Navy Yard Dispensary, saying that he "was all in," giving the following history up to the time of his present illness. Had never been sick until two years prior to this time, when he had an attack of so called acute rheumatic fever, for which he was treated in a naval hospital for some eight weeks, when he was discharged cured, and had remained so until a few days before his admission to the Naval Hospital, Portsmouth, N. H., October 1, 1914.

On July 27, 1915, inspection revealed a man 5 feet 6 inches in height, apparently well nourished, whose expression was one of suffering. He complained of inability to walk without extreme pain in both feet extending above the ankle joints. Upon examination, the parts presented marked swelling, redness, tenderness, and increase of heat. In all of the small joints of the feet and in the ankle-joints motion was markedly limited, and manipulation of the joints produced great pain.

His upper teeth had all been extracted some years previously, and were replaced by a fairly good plate, eight teeth were remaining in the lower jaw, imbedded in a mass of faulty gold bridge work, which was most unhygienic, with a large amount of pus exuding from around all teeth. No additional local focus of infection could be found. Weight 143 pounds stripped, normal weight 153, systolic blood pressure 150.

He was told that he had pyorrhea, which was probably the cause of his general condition, and I would only treat him provided he would do as directed by my dental associate whom I was sure would insist upon the removal of the faulty bridge at least.

He stated then "that he had been treated continuously for fifteen years for pyorrhea, by a number of civilian dentists," was very much astonished to hear that this condition was the cause of his "rheumatism," could hardly believe it, "as none of his former physicians had ever asked him about his teeth, much less looked at them." He was referred to Dr. White for dental examination, who told him the bridge must be removed and possibly all the remaining teeth might have to be extracted. He consented to our combined treatment finally. On July 30 injection gr. 5/5 mercuric succinimide; August 6, gr. 5/5; August 12, bridge work removed, all eight teeth very loose, the lower right second molar considered hopeless was extracted. Scaling of remaining teeth commenced; August 20, injection gr. 5/5 mercuric succinimide; August 27, gr. 5/5; September 2, pyorrhea pronounced cured by Dr. White, arthritis improved. Further injections continued as follows: September 3, gr. 5/5; September 10, gr. 5/5; September 17, gr. 5/5; September 24, gr. 5/5. By this time he had markedly improved, and the injections were discontinued for the time being. Graduated exercise of the feet was now commenced and gradually increased. November 3 injections renewed, gr. 5/5 administered. This produced rather severe abdominal pain and diarrhea. Injections continued as follows: November 10, gr. 1/2; November 17, gr. 1/2; November 24, gr. 1/2; December 1, gr. 1/2. At this time all symptoms had disappeared, motion was nearly complete in all joints and function practically restored to normal, weight 149 pounds, systolic blood pressure 122. Treatment discontinued.

On January 10, 1916, he was discharged from the service by expiration of enlistment, being certified by the medical officer who succeeded me on the *Southery* as physically qualified for re-enlistment, and was re-enlisted by him the following day. He now (February 14, 1916) weighs 158 pounds stripped.

1. Had the pyorrhea been cured fifteen years ago, this man in all probability would never have developed arthritis.

2. When the arthritis first developed, had a search been made for a local focus of infection, and found, and the proper treatment instituted, two months would probably have been the limit of his illness.

3. Had this been so the Government would have been saved many hundreds of dollars and the man much suffering.

4. The criminal fallacy of the therapeutic test for syphilis is apparent.

5. The inefficiency of the recognized treatment (salicylates and alkalies) in these conditions is apparent.

This assertion is sustained by the eminent men using Baccelli's treatment for acute articular rheumatism, as is well shown from the following abstract of Martone's article copied in full from the *Journal of the American Medical Association*, March 13, 1915:

"Intravenous Injection of Bichlorid in Acute Rheumatism.—Martone reports five extremely severe cases in which salicylic medication failed to influence the clinical picture or caused symptoms of intoxication so serious that it had to be discontinued. As a last resort he turned to mercuric chlorid and gave it by intravenous injections in doses from 1 to 5 mgm., repeated every day or so well into convalescence. All the patients given this treatment recovered, and none has shown any evidence of a return of joint trouble since. Only one was left with a slight valvular defect; in the others the endocarditis, if such existed, seems to be completely cured. He gave ten injections in one case, beginning with 2, 3 and 4 mgm., and increasing to 5 mgm., toward the end. In another three injections seemed to conquer the disease but he continued with three more on alternate days to make sure of the result. In another case no benefit was apparent under salicylates for a month, and then five injections of mercuric chlorid were given and the cure was soon complete. He followed Baccelli's technic in every particular." (Italics mine).

6. The marked curative properties of mercury in these conditions must be recognized.

7. If mercury had not been administered this man would in all probability have been discharged as incurable, becoming a navy pensioner for life, thereby costing the Government thousands of dollars, for which it would receive no return.

Conclusions.—From my results in this disease and in other infections previously reported, corroborated by the results reported by Souligoux, Giru, and Krohl in septic infections, and by Baccelli and his followers in infectious arthritis, I am convinced that in mercury, properly administered, we have found a cure for the various infections produced by the vegetable parasites, among which pyorrhea, as a primary focus of infection, is of the utmost importance.

The eminent men mentioned have only failed to recognize the advantage of the large doses recommended by me, hence the necessity for their frequently repeated and continued administration of this parasitotropic agent.

Shortly before the death of the lamented Ehrlich he prophesied that chemo-therapy would supplant all other forms of treatment of disease. I am confident that his prophecy will shortly be fulfilled.

NAVY YARD, PORTSMOUTH, N. H.

THE NURSE IN PEACE AND IN WAR.*

BY J. LEONARD CORNING, M.D., LL.D.

NEW YORK

It is not an easy thing, it would seem, to utter anything either very new or very inspiring upon nursing the sick, a theme that has been so often and so ably treated in the past, and more especially during the past thirty years. So I thought when it was suggested that I should address you on this well-worn subject. However, after an interval of reflection, it occurred to me that there were certain aspects of nursing—sociological, ethical—that might be touched upon without manifest triteness; and that looking at matters in this way might arouse in some measure an intensified and broader conception of the significance and dignity of the nurse, trained, zealous, and faithful in her work.

We are flocked this afternoon to pay tribute and wish success to those who are about to dedicate their lives to a high and useful calling—to tend the sick and the infirm, the sorely afflicted in heart, in body, or in mind. 'Tis a noble work! You who are about to give practical effect to the benevolence of the heart may hold up your heads. Be assured that your professions are not lost upon dull ears. Yours is no cramped espousal; the thing which you have set yourselves to do is as broad as human nature.

And you are well prepared. For many months, under favorable auspices, with invaluable opportunities, carefully led on by a corps of accomplished instructors, and solicitously followed in your undertakings by a sympathetic sentiment—for many long and arduous months you have unflinchingly pursued that discipline that alone could enable you skillfully and intelligently to carry on the campaign of the sick room under the generalship of the attending physician.

And now, in the ripeness of time, you are about to step into a world of action—into that world of strong contrasts, of shabby compromises, of ideals half smouldered, flickering up despairingly amid the smother of an ubiquitous selfishness. If perchance your own ideals flutter afflictively at the discovery that all the flowers of earth are not endued with fragrance, do not let that discourage you for long. Consider how men have gone forth to battle and women have braved the pestilence to staunch their wounds; how hungry scholars have achieved master-works in garrets; how moss has grown on a rock. Consider the public library and the hospitals of this city—all kindness and beauty; consider how their walls arose at the sovereign touch of high devotion.

*Read at an assembly of nurses about to give their services to the wounded in the Great War, April 3, 1916.

It has often been asked, "What are the personal attributes most desirable in an attendant on the sick?" The question is evidently answerable in a general sense only. Given good health, good nature, and a reasonable degree of technical training, it may be said that tact, adaptability—anything, in short, which confers power to accommodate oneself to environment, is of consequence.

A sense of humor, a capacity to enjoy the little discrepancies of human nature, is a great assistance in most situations, and is invaluable in the sick room. To be without this faculty is to miss those breaks in serious discipline, those vacations from the strenuous, so necessary to the preservation of serenity and poise. Remember that the planets will roll whether you smile or sigh.

To the physician upon whom devolves the generalship of the sick room, you will bring fidelity; to the patient, your skill, your tact, your hopefulness.

History shows that the disposition of a nation, like that of an individual, is subject to the vicissitudes of change. Contrast the exalted moods of Greece under Pericles with the crawling humors of her decline; think of Rome the republic and Rome the plaything of the Cæsars. Ours, too, it would seem, is in a measure a day of material expediency. Some of us think by boarding the express to pass poetry by, forgetting that she has wings. Just now convenience, luxury—tower high in the estimation of the slaves of the obvious. Beware of the false promises of a tinselled externality! Shall we miss the lesson of Egypt the great builder—Egypt the material? Shall we forget the grewsome relics of a vanity projected beyond the tomb—those spiced mummies, as dead as on the day when swathed and decked, they were laid aside, speechless recipients of a futile luxury? What a dismal heritage of despairing self-deception—this postponed rottenness, this sparkle of jewels on withered fingers, this dried laughter of a thousand years, of a death's head coffined round by porphyry!

To stand on the summit of the Great Pyramid is not to come very close to the zenith; yet an astronomer by looking up may know the secrets of the stars. Matter is changeable; those who feast do but pander to her fickleness. Kindness alone shall soften the harshness of the ages—kindness, boundless, like the inconceivable reaches of infinite space.

It is when brought low by a severe sickness that we feel these things the most. Ambition, zest, hope—all the desires and passions that in health we most tenaciously hold by—flee then, leaving naught behind but a poignant emptiness. Then it is that the nothingness of human achievement wails in upon our consciousness. A crushing sense of unreality conquers us completely; we seem mere phantoms, errant apparitions flitting at the whim of the inscrutable.

It is an arduous service, this which you have undertaken. During the long watches of the night and the drooping vigils of the early morning, when the tick of the clock sounds like the drop of leaden water, and a false twilight blends a spectral illumination with the boding hush—at that fainting hour of hope, when the pulse runs low and clammy fingers clutch the heart, turn your eyes to the east and know that presently the orb of comfort shall rise above the verge of the horizon to lay a halo of gold upon the head of one who has softened the suffering of the night.

Just now, and for more than a score of months, Europe has been the scene of such horror as has

not afflicted mankind since recorded time. Races, civilized in part and others in full measure, have set upon each other with the sanguinary madness of a pack of ravening wolves. Science has been despoiled, ingenuity made bankrupt to give effect to a ferocity that has sullied the fairest soils with the unnumbered bodies of the dead. And in every land, in all those mutilated by the sword and harried by a relentless spoliation, there are red eyes and hollow cheeks.

But this is but half the picture. Behind the trenches are the hospitals amid whose maimed and shattered tenantry move the nurses—an army of them—binding and soothing ever, pressed to their work by an irresistible plenitude of kindness. What a paradox! The passion which heals the wound seems as ardent as that which inflicts it.

Shall it be possible in the time to come to vanquish the combative by the milder instinct? May we look for an epoch in which the tone and organization of society shall be wholly altruistic? Not if history and present evidence count in the reckoning. Let the oversanguine scan their own hearts. And the bitter part of it is that the fighting instinct, horrible though it be in its collective and titanic manifestations, is at once an evil and a necessity. Without it no state worthy of the name could—in view of the constitution of the human mind and the moral limitations of the race—endure. History, the teachings of the life of every day, self-examination all point the same way.

What then of the nurse who labors among the sick, the wounded, and the dying? Are her works no more than chaff in a storm? Not if the quickening of all life by sunlight, or the fall of rain on the waste places of the earth count for something in the scheme of things.

Her function is, while relieving the pains of mankind as best she may, to set a term to the abuse of power, to offset the inevitable hardness of the world. Thus she shall keep the torch of benevolent aspiration alight, the glow of hope, the persistent expectation of the ultimate kindness of things so indispensable to the progress and sanity of the race.

THE REFERENCES TO ANATOMY IN RABELAIS' WORKS.*

BY DOUGLASS W. MONTGOMERY, M.D.,

SAN FRANCISCO, CAL.

IN many places in Rabelais' works there are wearisome enumerations of anatomical structures, principally citing the organs wounded either in a fight or in an accident. These lists of names, occurring as they do in a humorous writer, are presumably humorous, but in the present day it would take a confirmed admirer of Rabelais to find the joke, unless he sought out by sedulous study the contemporaneous meaning of the author. Many of the conditions of life and of thought are different now from what they were in the beginning of the sixteenth century, and the idea of what was ludicrous would vary with these conditions, and these jests may then have evoked the keenest interest and the most uproarious laughter.

Humor presupposes something serious to be humorous about, and this is probably the point in these lists of anatomical names. This will be taken up later, and in the meantime, to get a clear idea

*Read before the San Francisco County Medical Society, February 8, 1916.

of the subject, the following is a translation of part of the description of Friar John's attack on the despoilers of the convent garden, an incident in the war between Picrocole and Grangousier.

"Friar John came down upon them without a word of warning and knocked them over like a drove of hogs. He scrambled the brains of some, and broke the legs and arms of others, or dislocated the spondyles of their neck, or crushed their kidneys, jammed in their noses, poached their eyes, broke their jaws, sent their teeth down their throat, unhooked their shoulder blades, ruined their legs, dislocated their haunches, and disjoined their forearms. If any tried to escape among the vines he frayed the whole skin over their spines, and broke their back as he would that of a dog. He shattered the skulls of those who were fleeing by hitting them over the lambdoidal suture. Some daring ones showed fight, and it was then that Friar John put forth the strength of his muscles. He transpierced the mediastinum and the heart; he struck them under the short ribs and overturned their stomach, so visiting them with sudden death. Others he slammed so fiercely over the navel that their entrails burst out."

This is one of the most lively of these enumerations, but who would now consider this long anatomical list witty? Many on running across such passages lay down the book with a sigh. A physician may be interested in the old names, such as calling the *ulnæ les faucilles*, the sickles, especially if he happens to have been raised on a farm before modern machinery drove out the scythe and the sickle, and had learned to appreciate how the forearms of a good mower swing around as if a part of the implement he is handling.²

One explanation of the occurrence of these anatomical farces is that they were satires on writers who revelled in them. In fact, it is probable that Gargantua was modeled on old romances. A better one, however, seems to be the widespread interest, both popular and professional, that anatomy then excited. Anatomy was then a growing science, and the men engaged in it were animated by the enthusiasm of discoverers. Sylvius (1478-1555), Servetus (1509-1553), Vesalius (1513 or 1514-1564), and Fallopius (1523-1562), all lived in the time of Rabelais (1494-1553), or not long after, and they were the makers of modern anatomy. Besides this those who were engaged in the plastic arts and in painting were deeply concerned with anatomy.

The Plastic Arts and Painting and the Study of Anatomy.—Leonardo da Vinci (1452-1519), Michael Angelo (1475-1564), Rafael (1483-1520), and Benvenuto Cellini (1500-1571) were only the leaders in a vast art movement in Italy. Almost everyone was either painting like Leonardo da Vinci or Rafael, or carving in marble like Michael Angelo, or making castings like Benvenuto Cellini. This movement is comparable to the socialistic, mechanical, and chemical tendencies of modern life. The greatest artists were engaged in illustrating works on anatomy, and all of them strove through its practical study to attain artistic perfection. There are in the Victoria and Albert Museum in London wax models of muscles made by Michael Angelo,³ and I shall never forget Benvenuto Cellini's description of the beauty of the sacrum, the keystone to the pelvic arch, that supports the graceful upward curving vertebral column. In all probability he was as familiar as Michael Angelo with the lumbar muscles and the frame to which they were attached.

The illustrations in the old anatomies are interesting, as showing the close relationship between artists and anatomists. Very often, as frontispiece, there is a skeleton gallantly posed in the foreground of a landscape with the ruins of classic temples in the distance.

One of the finest of these frontispieces is "A Lecture by Vesalius" in Vesalius' magnificent "*Opera omnia anatomica et chirurgica*." The audience consists of boys, young men and women and old men. The preponderance of elderly men with flowing beards and long robes, as well as the elaborate architectural details were probably for artistic effect. The mixed audience, however, may indicate the popular nature of the lecture.

Even down to 1753 in Surgeon's Hall, London, iron spikes had to be fixed in the theater to prevent the mob from getting over the outer rail during the anatomy lectures,⁴ which shows what an intense interest the populace then evinced in these functions, for they were functions.

An anatomist, therefore, in Rabelais' time, had all those artists and their followers as enthusiastic and attentive hearers. And besides those who were studying these arts many also who were interested in theology were deeply concerned in anatomy.

Religion and the Study of Anatomy.—One of the most interesting anatomists of the renaissance was Servetus, who discovered the circulation of the blood one hundred years before Harvey. It is significant that Servetus' description of the circulation occurs, not in a medical work, but in the midst of a treatise on theology. His interest in anatomy bore on its relationship to his search for the seat of the anima, or soul, or spirit. To seek for this anima in the circulation and in the lungs was perfectly logical, for was it not written that after God had fashioned man of clay, He breathed into him the breath of life, and where else could He breathe it in but through the lungs? This idea of the soul or anima being a divine breath was an old and widespread one. According to Walter Pater, Marcus Aurelius speaks of it, saying that if there is a hereafter the divine breath will be there also.⁵ Servetus in seeking for the entrance of the soul into the body showed the characteristically daring practical tendency of the European investigator.

Besides the belief in the divine breath there was another belief that linked anatomy closely to theology, this was the mystic creed that there were soul or spiritual duplicates for the entire material human body, including every organ. This spiritual being was of an ethereal imponderable nature. In the *Inferno* reference is made to this. Of the two visitors in hell, Virgil and Dante, the latter was alive and corporeal. In their journey they met Chiron, the chief of the centaurs, who halted and regarded them narrowly. Then taking an arrow from his quiver, with its fork he musingly stroked back his beard, and turning to one of his fellow centaurs remarked, "Have ye perceived that the one behind," meaning Dante, "moves what he touches?" "The feet of the dead are not wont to do so." Even the deity was assumed to have a full complement of organs, such as appertains to the higher vertebrates, and it was customary to swear by those viscera. For instance, Rabelais swears, "*par la ratte Dieu*," by God's spleen.⁶

There was yet another point on which anatomy and religion touched. In accordance with the views then prevailing of the resurrection of the body, the theologians, who then held the chief political power,

were very strict in allowing bodies to be dissected. Very occasionally and after the performance of elaborate ceremonies, the body of a criminal might be obtained, and after dissection the remains had to be conserved for ceremonious interment.

When, therefore, we reflect that religion was then the subject of the most lively universal interest, and shortly led to one of the most devastating wars in Europe, the Thirty Years' War, and that religion was closely associated with anatomy in trying to fix the seat of the soul, we can get a faint inkling of the audience that an anatomist then had. The few lectures on anatomy that Rabelais himself delivered were given in the early part of his medical career, before the people of Montpellier, on the body of a criminal, and among those in his audience was Etienne Dolet (1509-1546), a writer and a politician, who was later burned for his religious or political views, which, as has been mentioned, amounted in those days to the same thing.

Therefore, through the great sentimental forces of both religion and art a vast number of people would be interested in anatomy, and in very many instances in an intense sentimental way, making it well worth while for a humorist to joke about it.

Not very far removed from the time when Servetus was so intently seeking for the place of entrance of the soul into the body, Rabelais described how Gymnaste killed Tripet, one of King Picrochole's men, by severing with a single stroke of his sword his stomach, colon, and the half of his liver. Tripet fell to the ground, and spilled out four pots of soup, and his soul was mingled with the soup.⁷ One of the prevalent beliefs then was that the blood was the soul, and the Great Mocker indicated that the unfortunate Tripet voided both the soup and the soul at the same instant and in a common stream.

The Practice of Medicine and the Study of Anatomy.—It was only natural that in a day when the study of anatomy excited such widespread interest that a reputation for special anatomical knowledge should substantially contribute toward a reputation for a knowledge of medicine, especially as anatomy was about the only real medical science then being developed. In fact, at present a medical reputation often does not depend on a man's knowledge of the care of the sick, but on a knowledge of some popular and allied subject, as bacteriology, or on his supposed acuteness in ferreting out rare diseases with strange and striking names. So the great anatomists of the Renaissance seem to have practised medicine. Vesalius was physician to Charles V and to his son, Philip II of Spain. Sylvius practised medicine, and Servetus, when he was not occupied in studying anatomy or engaged in some bitter religious disputation, was a practitioner. Rabelais also cared for the sick, but recognized that he could benefit the suffering ones more by jollying them than by any of the means then existing for the control of disease.

It is, therefore, no wonder that the lecturers in anatomy in those days had large audiences, exerted a wide influence, and gained considerable sums both in fees and as salaries. Sylvius, for instance, acquired a reputation for being miserly, and he could hardly have done this if he had not had the wherewithal to be miserly upon.

The whole understanding of medicine of that day was that of an art, the sole end of which was the cure of disease. The dominant idea of this art was that a physician gave a medicine, the specific effect

of which was the banishment or annihilation of a personal disease entity that was troubling the afflicted individual. It was almost exactly the same idea that the laity to a great extent yet has, as expressed in patent medicine advertisements. Of the various adjustments that can be made through a knowledge of the nature or course of disease, or through a knowledge of anatomy or physiology, they knew nothing, as these branches had not yet been sufficiently developed.

With the widespread knowledge of anatomy, and with its associations both fanatical and sentimental to religion and art, the ground was prepared for Rabelais' whimsical genius. For instance, Panurge in telling of his adventures in Constantinople, related how a Turk drew strips of pork through his flesh after the manner we do now in *bœuf à la mode*, and then tied him to a spit, and proceeded to roast him before a good hot fire. As burning alive was a popular form of punishment then and contributed materially to the entertainment of the people, this in itself was a kind of grim humor. The Turk, however, indifferent even to his victim's squirms and howls, fell asleep, and Panurge managed to free himself and to set the place on fire, and the owner of the house, rushing in, was so enraged that he drove the spit through the aforementioned Turk. Rabelais relates at length the parts pierced. The spit entered the belly, traversed the third lobe of the liver, pierced the diaphragm, entered the pericardial sac, and ran out near the shoulder blade. The only jokes I can see in the incident are the imperturbability of the Turk and a petulant remark made by Panurge as he was escaping from Constantinople as fast as his legs could carry him. It seems he was closely pursued by a troop of hungry dogs that acted as scavengers for that dirty city, and that were attracted by the savory smell of the strips of pork that were drawn through Panurge's flesh. Under these distressful circumstances Panurge observed that there is no pain of the teeth like that when the dogs are after you.⁸

It may be also that the slow roasting on a spit had a local flavor. In times previous to this, a condemned man was first strangled, and the body was then burnt. As the resurrection of the identical body was then a matter of faith, this added materially to the punishment, but in a way that was considered perfectly just and appropriate. As, however, toward the Reformation, the religious controversies became sharper, those condemned were burned alive. With the increasing controversial acerbity, the burning was more slowly done so as to increase and lengthen the suffering. In some instances a cage, containing the victim, was balanced on a long pole that was continually swept near the fire and away from it, making it resemble Panurge's experience with the spit. Calvin, as a typical exponent of his time and of his type of mind, caused Servetus to be burned with green wood, and the punishment was lingered out for a long half hour.⁹ Incidentally it may be remarked that Calvin and his doings were particularly detestable to Rabelais.

The attitude of the public toward anatomy has undergone a great change since the end of the fifteenth and the beginning of the sixteen century. General interest in this subject has steadily declined until now, even among medical men, the audience of an anatomist is diminishing. When I was a student those of us who became prosectors to the chair of anatomy were looked upon as being particularly fortunate, and the chair of

anatomy was always held by a surgeon. Well-known surgeons like McBurney and Bull were demonstrators in the dissecting room, and looked upon the position as being a stepping stone both toward a professorial chair and renown. All this is now changed. The anatomist in a medical school has nothing to do with surgery, and he teaches a branch that is looked upon as a preliminary study. Furthermore, connection with the chair of anatomy would now be considered detrimental to a surgical reputation. This estrangement of anatomy from the practice of medicine is not peculiar to this preliminary branch; it looks as if it would involve both chemistry and physiology, which are being built up into independent studies, so elaborately taught as to preclude a physician's participation in them. It is needless to point out the evils this course entails. The framework of the body, the functions adhering to that framework, and the chemical processes taking place within it should be the physician's constant study. Without them the physician as well as the surgeon becomes a technician, or a drug dispenser.

DEMENTIA PRECOX STUDIES.

THE RELATION OF CECAL STASIS TO DEMENTIA PRECOX.

BY BAYARD HOLMES, M.D.

AND

JULIUS RETINGER, Ph.D.

CHICAGO.

IN previous papers we have shown the parallel between the adrenalin reactions of dementia precox patients and the adrenalin reaction in persons and animals poisoned with the toxic amines, especially with ergotoxine, with histamine, and with indolethylamine. We have also shown that in dementia precox patients and in patients suffering with gastric crises of tabes, in both of whom this adrenalin paradox appears, the stools contain a load of histamine sufficient to produce a solution of 1:1000 in a cubic centimeter of water for each 100 grams of stool. No such quantity of this toxic amine is to be found in the stools of healthy persons or of those sick with other diseases having the normal adrenalin pressor action.

After this demonstration it became necessary to account for the production of histamine in these patients. Ross has shown that the indolacetic acid in the urine of dementia precox patients is four times as great on the average as it is in healthy individuals (83 to 21). He has further shown that it is greatest in catatonic cases (100), and that the quantity of indolacetic acid is not increased or diminished by the character of the food. Since indol-

acetic acid is obviously the result of catabolism of tryptophane, it might at first seem difficult to account for the fact that while indican is greatly increased in the urine by food of a high protein content, indolacetic acid is not so modified. It should be remembered in this connection, however, that tryptophane is furnished not only by the food but also by all of the secretions of the intestinal tract, from the salivary glands, the gastric glands, the mucous glands of the liver, and the secreting glands of the duodenum and small intestine. Ross considers the indolacetic acid "endogenous" in its origin, while the indican seems to be exogenous.

The same remarks apply also to histidin, from which histamine or betaiminazolyethylamine is catabolized, and the tyrosin from which ergotoxine is produced.

It is impossible to discover the products of the catabolism of histamine in the urine. This toxic amine is probably destroyed in the liver, but the form that it assumes is yet unknown. Ergotoxine is to be recognized in the urine in the form of paroxyphenylacetic acid, but the method of its recognition is difficult and not available in our studies. In the blood the recognition of ergotoxine has not proven practical with our patients, for their blood pressure is usually low and the blood contains a considerable quantity of histamine and a recognizable quantity of indolethylamine. By the method of Jolles the reactions have so far been positive, but frequently reactions of the same kind have been found when there was evidence that the indolethylamine was not present in the blood. It is well known that the three toxic amines individually and collectively increase the coagulability of the blood both *in vitro* (Zunz and others) and on intramuscular injections. The maximum of coagulability is far below the lethal dose of the amine. When the dose of amine is increased the coagulability diminishes and at last hemolysis sets in.

The difficulty of determining where these toxic amines are produced and what particular mechanism encourages their production has been solved in a large degree by previous researches. Arthur Keith has contributed to the study of this subject both from an experimental and from an anatomical standpoint. He has shown that there exists a series of sphincters in the intestinal tract dividing it into several lengths, each with a separate function. The first sphincter is in the pharynx; it is essential to deglutition. The second is at the cardia. The third is at the pylorus. The fourth is at the ileum, just as it empties into the cecum. The fifth is at the right of the middle of the transverse colon. The sixth and seventh are in the sigmoid and rectum.

It will be recalled by anyone with a clinical experience that quite serious spasms of the pharyngeal sphincter occur and require therapeutic attention. Hess has shown that this condition is quite common in the newborn. Spasm of the cardia is a well recognized clinical entity and is not easily forgotten by anyone whose misfortune it has been to treat such a case. Hess considers it present in many cases of spasm of the pylorus. In children the most common and the most serious spasm recognized today is pylorus spasm. It is frequently accompanied by spasm of the pharynx and spasm of the cardia, though few clinicians have reported this combination. Spasm at the ileum near its junction with the cecum has not received clinical attention in man, but it shows itself in John's disease in animals. The presence of the colic sphincter has been

emphasized by Cannon, who showed in experiments on animals that there was a contraction of this sphincter with each peristaltic wave in the transverse and descending colon, called the distal colon, coincident with an antiperistalsis in the proximal colon and cecum. By means of the barium meal the x-ray fluoroscopic examination exhibits this peristalsis of the distal and antiperistalsis of the proximal colon in a conclusive manner. The laborious work of James T. Case has confirmed all the previous experiments in this direction and has given a substantial basis to the clinical experimental work of Arbuthnot Lane. Normally, then, there is a sphincter dividing the colon into two portions and acting as a pylorus to a second stomach, the "cecal stomach." Spasm of the sigmoid and of Jacobson's sphincter results in Herter's infantilism and Hirschsprung's disease.

In our examination of the motor efficiency of the intestinal tract in cases of dementia precox we early discovered the spasm of the colic sphincter and the reduplication of the transverse colon between the hepatic structure and this sphincter. The number of patients that we have been able to examine has been too few to give this observation any great value and our opportunities have not been adequate to carry on this study. We have been able to examine the x-ray plates of a great many patients with the test meal in the cecum and proximal colon without discovering this reduplication very frequently. It certainly is not common in the healthy.

The long retention of the cecal contents was clinically looked upon by Arbuthnot Lane as the cause of a toxemia grave enough to require surgical interference. He was sustained in his therapeutic experiment by the teachings of Metchnikoff and by the bacteriologic work and chemical investigation of Nathan Mutch. Bertrand and Bertelot had discovered among the inhabitants of the cecum a bacillus which they termed the *Bacillus aminophilus intestinalis*, capable of growing upon a nutrient media containing one-half of one per cent. of histidin, and thus producing histamine, or betaiminazolyethylamine. The same organisms were discovered by Mutch in the cecums and colons extirpated by Arbuthnot Lane. He found that the ileum was practically sterile down to the sphincter and that the cecum was full of the growing colon bacilli capable of producing the toxic amine. He demonstrated by the methods of Dale and Barger the amount of histamine in the cecal contents. Clinically the implantation of the ileum into the sigmoid produced satisfactory results. Chas. A. L. Reed has performed the same or similar operations upon epileptics and has reported beneficial results.

Although the evidence is not all in—and were it in it would be impossible to collect it into this short article—we can say definitely that there is much evidence of the intoxication of the dementia precox patient with these toxic amines, and perhaps with others not yet recognized. The most easily recognized of them, the indolethylamine, has been demonstrated in a great number of dementia precox patients in its catabolized products in the urine, in the stool, and in the perspiration, and there is strong evidence that it has been recognized in the same manner in the blood. Intoxication with histamine explains many of the adrenalin paradoxes. The increased coagulability of the blood which is a conspicuous symptom in many dementia precox patients is consistent with amine intoxication. Many

patients have been operated upon for appendicitis at the beginning of their breakdown with dementia precox, and many others have complained for a long time before their breakdown of abdominal disturbance and they have given expression to toxic symptoms such as attend fits of biliousness and constipation.

If we were asked to interpret the origin of pylorus spasm we would doubtless mention the nervous temperament of the patient, the possibility of parathyroid deficiency, the possible deficiency of the calcium salts in the tissues, and especially the presence of irritation above the pylorus. Clinically, hyperacidity and ulcer of the stomach have been looked upon as causative factors and the washing out of the stomach before meals has resulted in diminution of the spasm. This has been especially the case in children where the psychological effect of the tube can hardly be brought forward. As to the origin of the spasm of the cecal sphincter, we have little to offer. Probably the same factors prevail. There may be a constitutional spasmophilia, but there is much more likely to be a local irritative cause either in the material poured into the cecum, the plancton of the cecum, or in irritation going out from the pylorus or duodenum through the musculoneurol ligament of Colin MacKenzie, which seems to be related to the nerve supply of the sphincter which initiates the peristalsis and antiperistalsis of the colon.

The clinical history, the physical and biochemical examinations, and the symptoms of dementia precox are consistent with a toxemia going out from the decomposing refuse of intestinal digestion in the cecum, where they have been long retained. The betterment which occurs in many cases of dementia precox during an attack of typhoid fever might be explained by working out this hypothesis.

It seems that any research on dementia precox ought not to neglect the study of the motor efficiency of the colon and its relation to the toxic amines.

THE CAUSATION AND TREATMENT OF PELLAGRA

BY H. E. BOND, M.D., M.C. (Cambridge), L.R.C.P. (Edinb.), L.R.C.S. (Edinb.), L.R.F.P.S. (Glas.)

LONDON, 1916

THE SEVENTH EDITION, THE MEDICAL SOCIETY, DEVON, AND THE MEDICAL OFFICE, NATHAN ASYLUM, CHICAGO, 1916

In the general interest evolved by the recent papers appearing on pellagra in the various medical journals of both continents, a short paper at this time may be of some value. Despite the various theories that have from time to time been advocated, I desire to bring to the notice of the profession the following theory, viz., (1) Gastrointestinal autointoxication (or alimentary toxemia). (2) Actinic rays of the sun.

The term gastrointestinal autointoxication has been under discussion quite recently as not being a correct one to use, but being an old term, and one more readily understood, I am confident that its use will be permitted. In discussing this subject, and in order to go into the matter as fully as possible, I propose to deal with it under the following headings: (a) Relations of the gastrointestinal tract to the skin. (b) Relations of other organs to the skin. (c) Relations of other conditions to the skin.

The Stomach.—There seems to me to be abundant evidence in favor of this relationship. The conditions *acne vulgaris* and *acne rosacea*, which appear on the face, tell at once that the stomach is at fault.

The Intestines.—Taking typhoid fever as an example, we are all familiar with the fact that between the seventh and the ninth day there appears on the skin of the abdomen reddish or rose-colored spots. Pathologically there is intense hyperemia of the intestines during the first week. Sir Malcolm Morris in a paper entitled "The Internal Secretions in Relation to Dermatology," quotes Sir Arbuthnot Lane as having described the pronounced pigmentation met with in cases of alimentary toxemia beginning under the eyelids and thence spreading gradually over the face. The neck first becomes brown and then almost chocolate colored. The skin of the abdomen, the thighs, axillæ, and that covering the spinous processes of the vertebræ grows progressively darker, and on these surfaces areas of a still darker staining may develop.

In an address delivered by Sir Arbuthnot Lane on "Chronic Intestinal Stasis," and published in the *British Medical Journal*, Nov. 1, 1913, he, in classifying the symptoms, makes the following statement:

"The symptoms that result directly from the auto-intoxication of chronic intestinal stasis. * * * No. 3. Degenerative changes in the skin associated with alteration in its texture and color, the development of pigmentation, especially in certain localities, and a more or less offensive character of the perspiration. The pigmentation is so marked in some cases as to leave little doubt that the patient is suffering from Addison's disease."

He also cites the following cases:

CASE I.—Suffering from general debility of four years' standing accompanied by symptoms of mucous colitis with alternating constipation and diarrhea. . . . There was marked yellowish-brown staining of the skin, which, in the association with the asthenia, suggested the possibility of Addison's disease.

CASE IV.—K. H., spinster, aged 37, had been constipated since birth. She had attended several different hospitals during the last eight years. She was said to have mucous colitis, and appendicostomy was done. She had been in the habit of taking 6 minims of croton oil twice a week, and said that this usually opened her bowels once. She had well-marked toxic symptoms, and was very pigmented.

CASE VI.—A. E., a married woman, aged 30, had been constipated ever since she could remember. She had been treated at five different hospitals. She had suffered severe abdominal pain for the last eighteen months. Toxic signs and pigmentation were well marked.

CASE XII.—A. P., a married woman, aged 54, had been constipated for six years, and always had indigestion. She also had attacks of vomiting, and for the last few weeks severe pain in the abdomen. The skin was very pigmented, and toxic symptoms were well marked.

Anatomy of the Sympathetic Nervous System.—We are well aware that the sympathetic nervous system is connected with the central nervous system by communicating and distributing fibers. The branches of communication between the ganglia are composed of gray and white fibers, the latter being continuous with those fibers of the spinal nerves which pass to the ganglia. The branches of connection between the ganglia and the central spinal nerves also consist of white and gray nerve fibers, which may be contained in separate filaments or united in a single branch, the former proceeding from the spinal nerve to the ganglion, the latter passing from the ganglion to the spinal nerve, so that a double interchange takes place between the two systems (Gray). Dr. S. A. Kinnier Wilson, in

an address published in the *British Medical Journal*, June 14, 1913, on the "Clinical Importance of the Sympathetic Nervous System," states that "it possesses this remarkable feature that it gives a double nerve supply to the skin and its appendages, the glands, vascular system, alimentary system from mouth to anus and respiratory system, due to the two divisions of the system, namely, the sympathetic and para-sympathetic, or autonomic. Traced into the cord we find that it is represented as the inter-medial lateral tract; further up to the brain it can be traced farther backwards than the basal ganglia. There is another important point in connection with the sympathetic nervous system, and that is the chromaffin cells, which are founded in the sympathetic ganglia and plexuses; also masses of chromophil tissue lying in depressions on the dorsal portions of the ganglia. In the chromophil system, therefore, we have a widespread tissue immediately allied to the sympathetic nervous system in origin and localization endowed with important physiological properties. Chromophil tissue secretes a substance which has a definite and characteristic action on non-striped muscle fibers; in other words, on structures which are innervated by the sympathetic nervous system."

The intestines are entirely supplied by the sympathetic nervous system through the superior and inferior mesenteric plexuses, these finally subdividing into Mesener's and Auberach's plexuses respectively, supplying the muscularia mucosæ which are composed of non-striped muscle fibers.

Physiology.—In a paper which appeared in the *Practitioner* of January, 1915, on the "Physiology of the Chromaffin System," Prof. D. Noel Paton, states: (1) The chromaffin tissue may be defined as a tissue composed of cells derived from the nerve cells of the abdominothoracic sympathetic system, which stain a brown color with chrome salts and produce a physiologically active substance called adrenalin. (2) The law that adrenalin acts by stimulating the endings of the true sympathetic nerve is universal—Elliott's law. (3) On the muscles of the alimentary canal in the doses usually administered in experimental work, adrenalin produces the effect of stimulation of the true sympathetic. (4) In considering the exact seat of action of adrenalin physiologists have perhaps too much ignored the terminal ganglia which in the case of the intestine at least have such important functions.

Pathology.—Dr. Mott of London, in his review of the histological changes of the nervous system in a case of pellagra, among other things states that the combined sclerosis is not unlike that found in a pernicious anemia which we know may be due to a streptococcal toxemia, etc.; moreover, my experience tells me that the nerve cell changes rather indicate a chronic toxemia.

Dr. H. F. Harris of Atlanta, Ga., in a paper on the "Pathology of Pellagra," which appeared in the *Transactions of the first National Conference on Pellagra*, held in South Carolina, in discussing the pathology of the brain says the following: "By far the most interesting communication that had up to that time been made on the changes in the brain was an article by Babes and Sion in 1899. They showed the presence in the nerve cells, particularly in the large chromophilic cells in the cortex, the presence of unmistakable changes, etc. The nuclei are frequently pushed to one side and lose their power of taking basic stains and present swollen

nuclei; the pigment in these cells is also dislocated, and instead of being around the nucleus lies scattered throughout the cell-body, etc."

These alterations have been in the main confirmed by Marinesco, Rossi, Richette, Grimaldi, and by myself in this country, and are of great interest and importance.

Spinal and Sympathetic Ganglia.—The ganglion cells of these structures exhibit changes similar to those found in the central nervous system, though they are not as a rule so marked. In a paper on "Nervous Histopathology of Pellagra," read at the second triennial meeting at Columbia, S. C., Douglas Singer and Lewis J. Pollock say: "Similar reactions were found in the posterior root ganglia and in the cells of the semilunar ganglia of the sympathetic and of Auerbach's plexus in the intestine where these were examined."

In the report of the Illinois Pellagra Commission it is stated that in Case II there was widespread chromatolysis of axonal type with marked pigmentary changes involving especially the larger elements. Pigmentary changes were present even in the medium size pyramidal cells, etc. Many of the cells, especially among the smaller elements, showed a diffuse dark stain which, with a heaping up of satellite cells, suggested the existence of a more chronic type of cell change. Similar changes were present in the Purkinje cells and the cells of the posterior root and sympathetic ganglia.

The Absorption of Toxin or Toxins from the Gastrointestinal Tract as a Causative Factor in Pellagra.—In the first progress report of the Thompson-MacFadden Pellagra Commission, Dr. W. J. McNeil, in his observations on the intestinal bacteria in pellagra, states that "in general it was ascertained that the fecal bacteria in pellagra when examined directly with the microscope are different from the normal in their quantitative relationship and that unusual kinds of bacteria more or less heterogeneous in nature are present."

In the summary of the same report by various authors under the heading "Symptomatology" the following statement is made: "It would appear that three or four years ago a large proportion of cases observed in the county presented intestinal and nervous symptoms of great severity. In 1912, in many instances, symptoms were quite mild, and sometimes were confined almost exclusively to the cutaneous system, the disease appearing to be of a less virulent type in 1912 than in previous years, also the feces contain decidedly abnormal amounts of indol and skatol, especially the latter."

"The feces of pellagrous individuals have a most characteristic aromatic odor, and the estimations of the indol and skatol would indicate that this odor was due to the large amounts of these aromatic bodies found to be present. Normally only traces of these bodies are present, and from the investigation of Herter, and also of one of us (Myers), with Fisher and Diefendorf, the amounts detected, especially of skatol, may be regarded as decidedly abnormal and indicative of peculiar bacterial conditions in the intestine. When these results are compared with the acidity determinations in the gastric juice, some relation between the amount of skatol formation and anacidity is apparent."

"Again the feces of pellagra individuals have a most characteristic odor, and the estimation of indol and skatol would indicate that the odor was due to the large amount of these aromatic bodies found to be present."

Dr. J. A. B. Hammond of the Isle of Wight, in reporting a case in the *British Medical Journal* of July 5, 1913, states that "when I first saw the patient the general impression was that of one suffering from a chronic toxemia, probably of intestinal origin."

In the post-mortem report we find confirmative evidence. In Dr. Mott's report of an Egyptian case related in the same journal, "the stomach was dilated and thinned with denudation of epithelium. The small intestines were normal in condition. Large intestines in condition of chronic colitis, with denudation of the epithelium and patches of marked congestion with ecchymoses and arborization of blood vessels."

It would seem quite possible that whatever may be the toxin or toxins in the gastrointestinal tract that may be the primary cause of pellagra, it is evident that these toxins act on the sympathetic nervous system in the intestines, then on the chromaffin cells and tissue, which by their close connection with the central nervous system produce the pigmentation called pellagra with its resulting degeneration and neuritis.

Relation of Other Organs to the Skin.—The Lungs. In pneumonia we have herpes labialis. In phthisis we have yellowish spots appearing in the region of the sternum—pityriasis versicolor.

The Suprarenals. The pigmentation in Addison's disease is an exaggeration of the normal, and occurs therefore in the face, the neck, the hands, anterior folds of axillæ, nipples, perineum and genitals, while in more advanced cases the mucous membrane may become pigmented (Rolleston). Pathological changes in the glands. (1) Atrophy of one or both glands. (2) The various stages of tuberculosis degeneration. (a) Interstitial growth. (b) Fatty degenerated patches. (c) Caseous masses.

The semilunar ganglia are degenerated and much pigmented, and they may through cicatricial contractions become entangled, as it were, in the diseased tissue of the adrenals. The nerve fibers show extensive sclerotic changes. Drs. Alexis and Arnaud assert that "Addison's disease will not result if the pericapsular ganglia be not affected, though the other portions of the adrenal bodies are at the same time extensively diseased." (Wheeler & Jack.)

The pituitary gland. There is pigmentation in this condition. Sir Malcolm Morris quotes Harvey Cushing as saying that in all his patients affected with primary hypopituitarism, except the older ones, the skin was smooth, transparent and notably free from moisture.

The thyroid gland. One of the signs of myxedema is the yellowish tint which the skin presents. Red patches may mark the skin over the nose and on the cheek. In exophthalmic goiter the skin may show a pigmentation closely simulating that of Addison's disease and leucoderma, severe pruritus, or urticaria. It may be well to note in passing that the suprarenals are supplied exclusively by the solar plexus, also that the thyroid gland is supplied entirely from the superior and middle cervical ganglia of the sympathetic nervous system.

The Relation of Other Conditions to the Skin.—The familiar pigmentary signs of pregnancy suggest that the sexual secretions may be concerned in normal coloration. The malignant cachexias of the various organs and the various anemias all seem to suggest that the skin is an index not only of the condition of the gastrointestinal tract, but also of that of other organs and different blood states.

The Actinic Rays of the Sun.—In the study of spectrum analysis there is what is known as the reverse dark line or absorption spectrum. Light transmitted through certain liquids as blood produces band spectrums; these spectrums are obtained only when light passes through mediums capable of absorbing rays of a certain wave length, hence they are called absorption spectrums. The sun also consists of a luminous solid, a liquid of intensely heated and greatly condensed gas called photosphere. From the above it would appear that there are factors in the sun's rays which can act as an irritant to the uncovered area of the skin, and so cause an intense hyperemia in the subject whose vitality is already lowered from defective nerve innervation.

Clinical.—Turning to the clinical side of pellagra we seem to find abundant evidence of the condition occurring in the spring and summer time even in the colder countries. In the case described by Dr. Hammond he states that "in the late spring of 1912 she (the patient) was taken out into the garden and for two or three days somewhat exposed to the sun; this was quickly followed by the appearance of an erythematous dermatitis over the back of the hands and wrist, the palms escaped, but on the wrists it crept round to the front as described by Dr. Charles Box; a little later it came on the cheeks and on the lips. At first we regarded it as severe sunburn, but soon bullæ appeared and there was considerable supuration, especially from the lips and between the fingers. A little later the tongue and mouth ulcerated."

Dr. Sambon, in commenting on Dr. Kay's case at Lymington, states that "when one considers all the foregoing points the appearance of the first eruption at the end of summer, its second appearance at the beginning of spring, and its third recurrence also in spring, the remission of symptoms and improvement during winter, the bilaterally symmetrical erythema with subsequent desquamation, the vertigo, tremor, etc., one cannot help coming to the conclusion that the case is one of pellagra."

Dr. Stephenson, in reporting a case at Prestwich, says: "At the end of May the skin on the dorsal surfaces of the hand and wrists got red, rough and scaly; the face was also involved, but to a lesser degree, the bridge of the nose and both malar regions. The conditions were at first thought to be severe sunburn, for some other patients were undoubtedly sunburned at the same time, but while all the others got better this case did not. . . . On July 13, the patient was exposed to bright sunlight and the hands were markedly reddened again. During July 16 and 17 she was kept in bed in a subdued light. On the 18th the fading color was noticeable. After being out again on the 19th and 20th her face and one hand had got a vivid red and she indicated that the skin felt sore. The other hand had been covered with a glove and it remained pale, the rash on the face and forehead being brighter than before."

Dr. Box of St. Thomas' Hospital makes the following statement: "The month was December and the typical eruption was not present, etc. I had an opportunity of seeing the child in May this year; the rash had made its fourth appearance and was very striking; diffuse dermatitis implicated the flush area of the face, tip of nose, and margins of the mouth, the dorsal aspects of the hands and lower third of forearm showed the pellagrous gauntlet, etc. She was described by the house physician as looking very well and 'sunburned' the skin of the affected parts being characterized as 'tanned.'"

Experimental.—Dr. W. H. Harris of Tulane University, New Orleans, referring to his experiments carried out on monkeys, observes that "Monkey No. 2 was inoculated on December 2, 1912, it remained apparently normal for a period of two months and in February 12, 1913, it was again inoculated with filtrates from another typical case of pellagra. Early in May it showed irregular patches of a copper turkey-red color about the face. On May 10, these patches were raised considerably, darkened, very dry, and more clearly defined; they extended across the nose and spread in wing-like manner on either side under the eye and over the cheek. On May 28 the skin lesions had become almost black and were beginning to scale."

Treatment.—The gastrointestinal tract ought to be thoroughly disinfected and with this aim in view the following drugs have been found serviceable: Internally: calomel, beta-naphthol, acetozone, salol. Externally: an ointment consisting of beta-naphthol, balsam of Peru, and zinc ointment; later, when the bullæ have burst and a raw surface has been left, tar, salicylic acid, ammoniated mercury, and zinc ointment can be applied. Diet: A well balanced diet; ripe bananas daily; ripe papaws. General: Keeping in the shade as much as possible.

Conclusion.—1. That pellagra is a disease akin to Addison's disease. 2. That the causal bacteria are in the intestines as indicated by the amount of indol and skatol present, and that it primarily affects the sympathetic nervous system and, secondarily, the central nervous system. 3. That there are factors in the actinic rays of the sun which can act as irritants to the exposed surface of the skin so as to intensify the condition. 4. That it responds to treatment by gastrointestinal antiseptics internally, and externally by the usual protective ointments.

I am indebted to Dr. D. J. Williams, Medical Superintendent of the Lunatic Asylum, Kingston, Jamaica, for facilities afforded me and for his encouraging interest.

CLIMATE IN THE TREATMENT OF PULMONARY TUBERCULOSIS.*

BY WALTER SANDS MILLS, A.B., M.D.,

NEW YORK.

PHYSICIAN TO THE TUBERCULOSIS INFIRMARY OF THE METROPOLITAN HOSPITAL; MEDICAL EXAMINER FOR THE NEW YORK STATE HOSPITAL FOR INCUBENT TUBERCULOSIS.

TWENTY-FIVE or thirty years ago, and up to the last ten or twelve years, perhaps, it was customary for many physicians hereabouts to direct their tuberculosis patients to go West for the benefit of the climate. The West meant anywhere west of the physician's home to the Pacific Coast. Other physicians sent their patients South, and that meant anywhere from Virginia to Florida. About that time, 1884, Trudeau, because of the great benefit he had personally derived from a sojourn in the Adirondacks, established his place at Saranac Lake. After that many particular spots in various places, for one reason or another, came to enjoy the reputation of being beneficial to the lung invalid. Many patients so sent away got worse and died. A few recovered. A large percentage of the patients should never have been sent away from home, because they were beyond the stage of help in any climate.

About ten years ago the publicity campaign for

*Read before the Essex County, New Jersey, Homeopathic Medical Society, February 18, 1916.

the prevention and cure of tuberculosis began to be vigorously prosecuted. The public was told in large type of the horrors of tuberculosis. It was told that consumption was contagious, until families were split apart because if one member coughed the others were afraid of him. The public was told that fresh air and forced feeding effected a sure cure; nobody need die of tuberculosis. Professional philanthropists and social workers almost made the public believe that the physician was not necessary; medication and change of climate were not necessary; and so an ad nauseam. Some members of the medical profession even became obsessed with some of these ideas.

At the present time I think the medical profession is coming to a more rational understanding of pulmonary tuberculosis, its symptomatology, and the care of patients suffering from it. But even yet many deplorable mistakes are made, both in diagnosis and in treatment.

To-night I shall speak briefly of the use of change of climate as part of the treatment in pulmonary tuberculosis. Several things are of importance in this connection, and all of them seem to me to be of equal value: (1) The physical condition of the patient. (2) The economic circumstances surrounding him. (3) The place to send him to. Now to discuss these three questions in order:

1. The Physical Condition of the Patient.—During the course of a year I have a good many cases of tuberculosis referred to me for an opinion as to the stage of the disease, and for recommendation as to what to do. I can best illustrate what I recommend by citing a few cases.

CASE I.—Civil engineer, aged 22. I was first called in to see this young man December 6, 1901. He was rather a large, fine looking chap with a good family and personal history. I found he had been engaged for several months on the construction work of the New York subway which was then building. His work was all under ground in a place without daylight and always damp. He had had a succession of colds and had lost ten pounds. After watching him for several days and looking after a catarrhal pneumonia, I diagnosed infiltration of the right apex. Fine râles could be heard over that part of the lung above the scapula. On December 12 I called the late Dr. J. W. Dowling in consultation. He confirmed my diagnosis of pulmonary tuberculosis in an early stage. The patient was advised to take a trip through New Mexico, Western Texas and old Mexico. As his means were ample this was carried out. After four months he returned in first class condition, and has remained so ever since. He is now married and has several children, all healthy.

CASE II.—Woman, aged 32, born in Tennessee. A younger brother died of tuberculosis in 1902 or 1903. The family then came to New York to live. In 1906 this girl became my patient. Early in July of that year she weighed 113 pounds. She had developed a cough with some expectoration, was hoarse, and ran an afternoon elevation of temperature. I thought I detected evidence of trouble in the right apex. After having the patient under constant observation for a month, Dr. Pulley was called in consultation. He confirmed my diagnosis of early tuberculosis. As the brother had died after a few weeks in Arizona, the family was averse to sending my patient away. Arrangements were therefore made to keep her on the roof of the apartment house where she lived for six to eight hours a day, resting in a steamer chair. The progress was very slow. I kept constant supervision over her till January, 1907, when I was told she was to be married in a few days to an old sweetheart who lived in her Tennessee home. The wedding took place without my advice and the bride went to Tennessee to live. There I was told she went down hill rapidly until the local physicians despaired of her life. Then I was called into the case again by mail. My advice was to go to Albuquerque, New Mexico, and place herself under Dr. J. H. Wroth, whom I knew personally. This was done in May or June, 1907. Dr. Wroth in-

formed me that the patient's voice was gone, that her lungs were involved, and that he considered the case hopeless. The patient was at once placed in a sanatorium and for months was in bed. She remained in Albuquerque nearly three years. She was then practically well, but on my advice traveled for several months more, going as far South as Mexico City. Since 1910 she has lived in Tennessee a well woman. Every summer she comes to New York to visit her parents. In December, 1914, she had a child, born dead. This past summer, 1915, she spent in New York. She weighed 150 pounds and was in perfect physical condition. I believe the climate of New Mexico saved this woman's life.

CASE III.—Man, aged 49. Referred to me by Dr. E. Rodney Fiske, of Brooklyn, April 2, 1909. This man was a graduate of Annapolis, although then in business. Both parents had died of tuberculosis. The patient had a camp in the Adirondacks, and spent several months there each year. Notwithstanding that he had tuberculosis in the early stages in the right apex. The sputa contained tubercle bacilli. He had an open-air sleeping porch built on his house and proposed to be cured, if possible, at home. I advised a trip through the Southwest. I told him he must get away from business altogether for a time. He did so. He was away three months in New Mexico; that summer he spent in the Adirondacks. He has been well of his lung condition ever since. The tubercle bacilli disappeared.

CASE IV.—A woman of 30, sent to me for diagnosis in May, 1913. She was married and had one child, aged 10. She was a large, handsome woman, the picture of health. She had a slight cough. When I came to examine the lungs I was amazed. I found both were actively affected and ordered her home and to bed. I was unable to impress either the patient or the family with the gravity of the situation and my advice was not followed. In December of that year, 1913, the patient lost a brother with tuberculosis. That frightened her and I was sent for. Her home was in Newark. That time the patient went to bed and a nurse was called in to care for her. For three months I saw her once a week. There were no symptoms apparent to the uninitiated except a shortness of breath. But the patient had an elevated temperature all the time, and repeated examinations of the lungs revealed active lesions of both sides. There was no emaciation and the patient was still very beautiful to look at. The patient and the family urged me to send her away. I refused, on the ground that she was too sick to be benefited. Wherever she went she would need be a bed patient, and the absence from friends and home would more than counterbalance any benefit of climate. I was dismissed in April, 1914. The patient was soon sent away from home and died away from home in August, 1914. I do not think this patient had a fighting chance from the time I first saw her.

CASE V.—A young woman, aged 22 at time I diagnosed tuberculosis. She had been a patient of mine when ill since she was 6 years old. Practically all her sickness during these years consisted of an occasional cold, usually with sore throat. The family history was good so far as tuberculosis was concerned. In December, 1912, after a busy social season and a succession of colds, with slight cough and constant daily rise in afternoon temperature, I diagnosed infiltration of one apex. I told the parents one Sunday afternoon that the daughter had tuberculosis and must go away from New York. As the girl had some relatives in Montana I was prevailed on to let her go there. She remained away until the following September, 1913. She came back looking well, but without much change in the lung condition. She is quite tall and at that time weighed 115, much under weight for her height, but of a fashionable slowness. In the fall of 1913 a younger sister had typhoid fever. When this patient had recovered I advised the mother to take both daughters away. They spent four months in San Antonio, Texas, and another two months in various parts of Western Texas, returning to New York in the summer of 1914. My tuberculosis patient is cured. Her weight now is 150.

I think these few cases are sufficient to illustrate my point as to the physical condition of patients whom it is desirable to send away.

2. The Economic Circumstances Surrounding the Patient.—It must be remembered that a patient suffering from tuberculosis is sick. He needs all of the necessities and some of the luxuries of life.

The three things most needful in the treatment of tuberculosis are rest—mental and physical, fresh air, good food. These things cost money. Work and worry must be eliminated so far as possible. That again means money to care for the patient and to care for those dependent on him.

If a patient presents himself, therefore, who so far as the physical condition is concerned seems a fit subject to send away from home, his financial status must be inquired into. Climate will do no good if he has to go to work when he reaches the desired place. If he has to worry about how the family is going to get food and shelter when he is away climate again will do no good. In either case he should stay at home. All of the well known resorts for tuberculosis patients are over-crowded with health seekers looking for jobs, and many of them rapidly grow worse and die because of lack of proper care. When it comes to public charity, most communities are willing to care for their own, but they resent having outsiders foisted on them and refuse to care for strangers. I have had quite a good many patients in the Metropolitan Hospital, workmen or women, who have been sent West by some lodge or labor union, or perhaps by friends, but without funds to take care of them when they reached the sought-for place. They were promptly sent back broken in spirit and in physique, only to die. No patient should be sent away who has not sufficient funds to keep him for at least six months; a year is better, and with money enough to get home again at the end of that time.

Within the last two or three years the United States Public Health Service has investigated the "Interstate Migration of Tuberculosis Persons" and very great stress is laid on this phase of the subject. Texas and New Mexico were investigated and reported on by Passed Assistant Surgeon Ernest A. Sweet, North and South Carolina by Surgeon A. D. Foster.

In New York City charity cases are cared for by the local public charity officials. Very sick patients are sent to the Tuberculosis Infirmary of the Metropolitan Hospital, those less sick to the Sea View Hospital on Staten Island. The city Department of Health maintains a sanatorium at Otisville, about fifty miles from New York. The State maintains a sanatorium at Ray Brook, in the Adirondacks, for incipient cases only. New York City sends more than two hundred cases a year up there. The social and economic status of cases for all of these institutions except one is investigated by the social service of the Department of Public Charities. Cases sent to Otisville are investigated by the Department of Health. The physicians have to pass only on the physical condition.

3. The Place to Send the Tuberculosis Patient to.—My own preference as to climate for the tuberculosis patient is New Mexico and western Texas. Many patients do well in Colorado, but it is too cold for a good many invalids up there.

New Mexico and western Texas have a maximum of sunshine, the greatest of all germ destroyers, and a minimum of rain. The altitude varies from two to five thousand feet, and that is a desirable factor. The air is dry and, to my notion, has a distinct beneficial effect on the lung invalid. I spent nearly a year in that country for my own health twenty years ago, and I know whereof I speak.

The other places that are famous but nearer home I have not so much faith in. The lung invalid, if not too sick, will do better in the country away from

tenements and crowded streets and city life generally, no matter where it is. But I do not believe that the true curative air is either in the Adirondacks or in the Carolinas, or in the other places that have a great reputation, except in the places I have mentioned—New Mexico and western Texas. The other places are of benefit because patients sent there are removed from vicious habits or surroundings. When I say vicious, I mean physically vicious, unhealthful, not wicked. Sanatoria are numerous, but most of the health seekers who go to them are benefited by the right living and by the care they receive rather than by the air they breathe.

In New Mexico and western Texas I believe the air itself is of curative value. In any of these places the health seeker should place himself under the care of a local physician. That is likewise essential. Many lung invalids derive no benefit from a change of climate simply because they depend on the climate alone and do foolish things. The health seeker should place himself under competent medical supervision in his new habitat in order that he may know how to get the greatest benefit from his new surroundings.

10 EAST FORTY-FIRST STREET

A URINARY TEST FOR SYPHILIS AND ITS COMPARISON WITH THE WASSERMANN REACTION.

BY CARL D. GRAY, M.D.,

PORTLAND, MAINE

HOUSE SURGEON, MAINE EYE AND EAR INFIRMARY

THE form and variety of symptoms, either recent or remote, that may be produced by the *Treponema pallidum* are multiple. This same parasite causes certain metabolic changes in the human body, as is shown by the different laboratory methods, *i.e.* the Wassermann reaction, the gold chloride test, and the luetin reaction. With the exception of the latter, these tests require a well-equipped laboratory and reagents which are not within reach of the general practitioner. That some simpler test may be used which will at least strengthen or weaken the question in the physician's mind, is very probable. I wish to report a series of urinary examinations, part of which have been carried out in common with the Wassermann reaction.

The test is simple, requiring only a few test tubes, one of which must be graduated in cubic centimeters, and two stock solutions. A specimen of fresh urine, acid, in reaction and normal specific gravity, *i.e.* above 1.016. A test for sugar, even in the smallest amount, should also be made, as its presence will interfere with the reaction. The reagents consist of: Solution I, Dissolve 1 gram of resublimed iodine in chloroform or carbon tetrachloride; Solution II, Phosphoric acid 10 per cent. To perform the test take 6 c.c. of fresh urine, preferably the early morning, and add 1 c.c. of Solution I and shake thoroughly for two or three minutes. The reaction depends upon some substance which inhibits the decolorization of the iodine. After urine and iodine solution have been thoroughly shaken, the tube is set aside for a few moments, when the chloroform will settle to the bottom, being either pearly white (a negative reaction) or colored pink or deep purple, when the reaction is positive and syphilis is to be suspected. One cubic centimeter of Solution II is then added, and the tube and

contents are shaken the second time. If the chloroform is cleared and becomes white after standing three or five minutes, the test is negative.

The presence of sugar, even in the slightest trace, will produce a positive reaction, as has been proven by the examination of diabetic urines, and also by producing temporary glycosuria in healthy individuals whose urine had given negative tests and gave further negative reactions after eliminating a superabundance of carbohydrates from the diet.

A low specific gravity urine of the type produced by ingesting large amounts of water or the so-called "nervous polyuria" will give a positive reaction. To prove this, examinations of fresh urine from normal persons were made and were found to be negative; then later in the day, after several hours of labor with little or no water ingested, followed by copious drafts of fluid and a relaxation from mental strain, a second examination gave a positive reaction. This was illustrated in the case of several physicians after several hours' work in the operating room and in students following examinations. A positive result may also be caused by drinking one or two bottles of beer within a few hours of making the test. It seems necessary to inquire regarding the use of alcohol in this test for the same reason that it is necessary before taking blood for a Wassermann, the reverse result occurring in the urinary reaction. The presence of albumin, bile, indican, or blood has no influence upon the reaction. Cystitis, due to staphylococci, streptococci, pneumococci, or colon bacilli does not give rise to a positive reaction. Nor does gonorrheal urethritis unless complicated with a chancre. The reaction has been obtained from the urine of five patients where the diagnoses were made by finding the spirochetes with the dark field illumination. In other cases the diagnosis has been from the history and clinical finding alone or as controlled by the Wassermann reaction. In two cases all three of these reactions were positive without any history of infection obtainable, the only lesion showing in the mouth.

TABLE I.

Diagnoses	No. Cases	+	-
Syphilis	50	50	0
Surgical conditions	55	1	54
Tuberculosis	15	0	15
Glycosuria	5	5	0
Pneumonia	5	0	5

Gonorrhea	5	0	5
Kidney disease	15	0	15
Scarlet fever	2	2	0
Chromoma	3	0	3
Healthy individuals, controls	13	0	13
Polymorphous nervous origin	5	5	0
Polyuria produced by the use of diuretics	10	10	0
Typhoid fever	5	0	5
	200	75	125

This short report is based on investigations made only during the past five months, but a glance at the two tables will give a slight idea of the results obtained. Urinary examinations were made in two hundred cases from patients suffering from different diseases as diagnosed under Table I, while it was possible to make a Wassermann for comparison, as is shown in the thirty-five cases in Table II. It has not been possible to obtain urines from cases of every description, and it is very likely that a more thorough investigation will show other conditions besides those noted below which give the reaction. With the results obtained it would seem

that, while the test does not afford a positive diagnosis for syphilis, it has its place in the examinations, and in certain cases might aid greatly in determining a more elaborate test.

The cause for the reaction is unknown as far as I have been able to determine. Physiological chemistry has not as yet solved all the problems or given cause for all reactions that occur. From results obtained in different tests we assume that certain substances, in some unexplainable manner, react with other substances and cause a definite result.

For illustrative purposes, I will cite a few case histories for comparison of the results tabulated in Table II.

CASE I.—J. R. D., man, age 31, widower. Wool sorter. Family history, negative as far as obtainable. Has three sisters, four brothers living and well, although one brother, aged 43, is nearly blind. Has always been in good health, never been under treatment for any cause. Complaints of difficulty in seeing things after dark. First noticed this about five years ago. Onset gradual and vision perfect during the day. Examination showed the lids, sclera, cornea, and pupils normal. Through the ophthalmoscope both disks were pale, the vessels small, and pigmented areas all over the retina. O.D.V. = 1. O.S.V. = 1. Clinical diagnosis of retinitis pigmentosa O.U. was made. Urinary test was very positive and the Wassermann showed + + +. Under mixed treatment improvement was marked in three months.

CASE III.—V. M., woman, age 18. Single. Book-keeper. Family history: Father living, in poor health, cause of which the patient does not know. Mother died eight years ago of tuberculosis. One brother and one sister living and well. Four brothers and three sisters died soon after birth, cause unknown. Always been well till March, 1915. Has had severe frontal and occipital pain the last six months and lost some weight. Has lost all her teeth. Last March the left eye began to get red and painful. Photophobia. Vision lost within a week. Was in Canada at that time but returned home in the summer. In August the right eye ran the same course, and she lost weight and became almost totally blind. Entered hospital first of November. Examination showed the cornea dull, with dense infiltration. Pupils contracted. Deep circumcorneal injection. Perception of light only. Clinical diagnosis of interstitial keratitis and iritis. Urinary test positive, Wassermann + + +. Under treatment marked improvement has been noted, vision returning slowly.

CASE IV.—C. S., female, age 18. Single. Family history: Father died fifteen years ago of tuberculosis, age 33. Mother died four years ago, at the age of 42, from a shock. Two sisters living and always been well. Has had pneumonia eight times. Suffers from dull headaches and has been obliged to wear glasses. Otherwise always been in good health. In the middle of June, 1915, a rock struck her in the face and broke her glasses, a small piece going in the left eye and being removed. A week later the eye began to smart and burn, vision growing dim. A week later the right eye began to fail in the same way. Condition grew worse, till it was impossible to tell day from night. Examination showed the cornea deeply infiltrated, gray, and hazy. Pupil small and immobile. Patient had to be led about. Clinical diagnosis of interstitial keratitis and iritis was made. Urinary test was positive. Wassermann + + +. Under treatment the condition improved slowly.

CASE VII.—O. C. H., male, age 29. Family history negative. Had a chancre in 1898, followed two months later by a rash all over the body. Was told at that time he had syphilis. Took mercurial and mixed treatment for two years. Spent three months in a sanatorium for tuberculosis which involves the upper portion of the right lung. Three weeks before being seen (September 3, 1915) the right eye began to feel irritated, got red and painful. Photophobia. Examination showed the cornea dull, with infiltrated areas and deep injection. O.D.V. = 0.5. O.S.V. = 1.2. Diagnosis: Interstitial keratitis. Urinary test positive. Wassermann negative. Under treatment the condition improved rapidly.

CASE VIII.—Mrs. P. P., age 52. Married. Family history negative. Always been well. Mother of twenty children, three living, seventeen dying under 1½ years of age. The left eye has been sore and painful for the

TABLE II.

Case	Clinical Diagnosis	Specific History	Iodine Test, Urine	Wassermann
1	Retinitis pigmentosa	None obtained	+	+++
2	Uveitis acuta specific	None obtained, except for an attack of rheumatism	+	+++
3	Interstitial keratitis and iritis specific	None obtained	+	+++
4	Interstitial keratitis and iritis specific	None obtained	+	+++
5	Interstitial keratitis	None obtained	+	+++
6	Interstitial keratitis	None obtained	+	+++
7	Interstitial keratitis	Chancre and rash in 1898, 24-yr. treatment	+	+++
8	Iritis	None obtained	+	+
9	Interstitial keratitis	None obtained	+	++
10	Paralysis, third nerve	None, except for a rash a couple of years before	+	+++
11	Interstitial keratitis specific	Gumma of clavicle three years before. Received 2.1 gm. neosalvarsan. Took mercury for several months 14 years before	+	+
12	Paralysis third nerve specific	None obtained	+	++
13	Parenchymatous keratitis	None obtained. Has typical notched teeth	+	++
14	Paralysis external, rectus specific	Severe sore throat and rash two years before. Two miscarriages.	+	+++
15	Absolute glaucoma	None obtained	+	+
16	Scleritis conjunctivitis	None obtained		
17	Paralysis of superior oblique and inferior rectus	Attack of grippe about a month before		-
18	Parenchymatous keratitis	None obtained	+	+++
19	Episcleritis	None obtained	+	
20	Chancreoid	Sore on glands two years before. Bubo	+	++
21	Not reported	None obtained except for three miscarriages at two months	+	+
22	Gumma of neck	Chancre several years before	+	+
23	Interstitial keratitis	None obtained	+	++
24	Secondary syphilis	Ulceration of cervix and labia. Rash of face and body	+	+++
25	Interstitial keratitis	None obtained. Hutchinson's teeth	+	+++
26	Neurochoro-retinitis	None obtained, except for a sore throat a year before and slight rash on chest	+	
27	Keratitis	None obtained	+	
28	Neuroretinitis	None obtained	+	
29	Interstitial keratitis and iritis	None obtained	+	
30	Interstitial keratitis and iritis	None obtained. Hutchinson's teeth. Prominent frontal bone. Skin of hand dry and wrinkled	+	+++
31	Interstitial keratitis	None obtained	+	+++
32	Gumma of neck	None obtained	+	+++
33	Syphilis primary	None obtained. Mucous patches on labiae	+	+++
34	Syphilis of throat	None obtained. Mucous patches in throat showing spirocheta, enlarged glands	+	+++
35	Keratitis and iritis specific	Rash three years ago	+	+++

last two weeks (seen September 20, 1915). Cornea dull, infiltrated pupil, small posterior synechia. Diagnosis of keratitis and iritis. Urinary test positive. Wassermann + + +.

CASE XXIV.—Mrs. J., age 37. Family and past history negative. Ten weeks before (seen November 26, 1915) had been troubled with ulcerations of cervix and labia, which had healed under local treatment. When seen the face, arms, and body were covered with a macular rash. Hair falling out. Mucous patches in throat. Diagnosis: Secondary syphilis. Urinary test positive. Wassermann + + +.

CASE XXV.—D. D., female, age 12. Family and past history not obtained, except that she had been operated on for enlarged tonsils and adenoids. Referred from school. Left eye red and deeply injected. Cornea dull and infiltrated. Notched teeth. Skin of hand dry and wrinkled. Rash around mouth. Interstitial keratitis. Urinary test positive. Wassermann + + +.

In the limited number of cases which have come under observation, as is shown by the results obtained in Table I of 200 cases, the reaction would almost seem a positive diagnosis for syphilis, were it not for the fact that other conditions may give the same reaction. The presence of sugar can easily be ruled out by any of the laboratory tests and the use of any diuretic can be discontinued for a short period. The best method is to obtain a sample of the early morning urine, and do the reaction before decomposition has set in. A low specific gravity urine (below 1.015) usually gives a positive reaction, and the result of one examination in such a case should not be relied upon. In comparing the results in Table II, the most prominent point in favor of the value of the reaction lies in the fact that no case in which the history or clinical findings suggested syphilis has there been a negative urine reaction and a positive Wassermann; while in six cases the iodine test was positive and the Wassermann negative. Three cases in which both tests were negative and in which specific infec-

tion was not suspected are also tabulated. Three or four cases in which the urinary test was positive and clinical finding suggested specific infection have been under treatment and with marked improvement, although there was no Wassermann obtained. One case, which is not reported in either table, gave a positive urine reaction, also the spirochetes were found from the initial lesion with the dark field illumination.

In conclusion, it seems that in suspicious cases this simple test may aid greatly, either suggesting the use of a better established test or the cautious administration of antisyphilitic treatment.

THE INTRAVENOUS ADMINISTRATION OF MERCURY IN SYPHILIS.

By THAD SHAW, M.D.,
SAN ANTONIO, TEX.

THIS method was first used by Baccelli in 1893 and subsequently by Blaschko, Lewis, Chopping, and others. In recent years the method has apparently fallen into disuse. Very little is found in literature upon the subject, but since the popularization of intravenous medication in the usage of salvarsan and neosalvarsan this method of administering mercury has been revived. Two articles upon the intravenous injection of mercury in the treatment of syphilis have appeared comparatively recently; these are by Meyer, whose results were disappointing, and Lydston, who was very gratified by his results in eight cases. Wernigk after twelve years of experience appears enthusiastic. Balser, at the French Medical Congress in 1904, indorsed this form of medication for cerebral and ocular syphilis. Ravant uses the cyanide of mercury intravenously as a preliminary to salvarsan

therapy. Kingsbury and Bechtet write: "Our experience with this method is derived from the use at the New York Skin and Cancer Hospital in a large number of cases of cutaneous syphilis. We first used the bichloride in doses of one-sixth to one-third grain in distilled water. On an average six injections were given in each case. Our best results were attained with this salt. We used also the benzoate in a 1 per cent. solution of normal salt, of which the dose was 2 to 12 c.c. While the results with this salt were good, they were inferior to those obtained with the bichloride."

The use of this salt of mercury as an efficient form of antisyphilitic medication was suggested to me by Dr. Shropshire, who gave me a reprint of an article by an Alabama physician. And as the availability of salvarsan was fast decreasing, and as such had always been too costly so far as certain classes of patients were concerned, especially the Mexican who applies at the free clinics, and for routine use in the municipal out-patient departments, we decided to begin the use of mercury salts intravenously; we entered upon this work at the City Hospital with the idea of determining a definite average dose and time of administration, in all of which work we have been ably assisted by Dr. Barrow, who has undertaken the active administration of the medicine.

We first used the bichloride of mercury in physiological salt solution in doses of 1/12 to 1/8 grain of the bichloride in 10 to 20 c.c. of the salt solution. We found, however, that unless this solution was prepared fresh immediately before the administration, the patient presented from one to six hours after receiving the medicine very alarming symptoms, such as chill, temperature 102° to 104° F., pain in the abdomen, bloody stools, retention of urine, albuminuria in some cases, nausea and vomiting, together with headache. This reaction was due to the breaking up of the bichloride into calomel and HCl, and not to contamination by live or dead bacteria or by bacterial products. All references consulted, however, insisted upon the use of the sodium chloride in the intravenous solution to prevent the laking of the blood. Upon consulting my notes from the Oppenheim clinic in Vienna, I found the following method used:

Bichloride of mercury,	0.20
Sodium chloride,	0.30
Distilled water,	100.00

Give daily 1 c.c. intravenously.

The effects were quick. The patient got practically 1/30 grain bichloride per day. I do not remember having seen any bad effects, local or constitutional. Schumacher in his "Therapeutics" gives a formula recommended by Pyle as follows:

Bichloride of mercury,	gr. xv
Sodium chloride,	gr. xlv
Water,	Oil, 5 xiv
Dose: 1/16 to 1/6 grain of the bichloride.	

At the time of the first few injections we met with phlebitis and some periphlebitis following the administration of the medicine. Because of this and the unpleasant reactions we had experienced we decided to adopt another plan of procedure.

We first sought another salt; we tried the succinimide of mercury, but the irritation and the slough caused by this salt whenever the subcutaneous or perivascular tissues were invaded were almost as severe as those caused by salvarsan. Along about this time, and for the same reason,

some of the assistants at the Southwestern Insane Asylum began the use of the biniodide of mercury, and have had no unpleasant results from its use; but I am not familiar with the clinical results. However, knowing the greater value of the bichloride of mercury, and wishing to obtain more free soluble mercury in contact with the spirochetes, we decided upon another plan. We began the use of the bichloride in the same dosage in distilled water, regarding as nil the danger from the laking of the blood from the intravenous use of distilled water. Since this method of procedure has been adopted no unpleasant experiences have been met with. Of course, there is always a low grade of phlebitis, which becomes very marked after repeated use of the same vein and which gradually leads to obliteration of the vein; but this of itself is no inconvenience either to the patient or to the doctor, owing to the great number of accessible veins in the body. The dosage arrived at by us was 1/8 to 1/6 grain to patient of 140 to 150 lb. body weight every five to seven days. Usually the initial dose is 1/12 grain, after which, if there are no bad effects, the dose is increased gradually to 1/8 to 1/6 grain at intervals of every five to seven days, the number of doses depending upon the effects obtained and the Wassermann reaction. It was not always possible, however, to make a Wassermann test. At first a uranalysis was made in all cases the day following the administration of the mercury, but as no albuminuria was produced in any cases except those mentioned this was not strictly adhered to in all cases.

The results attained were exceedingly gratifying, as the following reports of the more interesting cases, from the Ambulatorium of the City Hospital, will show:

CASE I.—M. C., Dr. H.'s patient.—Syphilitic keratitis, hereditary. He had had three doses of 606, several months of mixed treatment, and potassium iodide. Wassermann was 3 plus; 4 plus after eight doses of 1/6 grain; the first dose caused a slight diarrhea. After fourteen doses the Wassermann was plus-minus and after fifteen doses was minus-plus. The patient's vision is considerably improved and he says his eyes are all right now. Case previously reported.

CASE II.—S., Leg ulcers; Wassermann ++++; first injection caused chill and temperature 100.8°. After ten injections the ulcers were halfway healed; patient was lost track of.

CASE III.—S. G., Ulcers of the mouth; Wassermann 4+. Four injections of 1/6 grain. Ulcers entirely healed.

CASE IV.—Lopez, Cerebrospinal syphilis. Wassermann positive. Symptoms somewhat relieved by three or four injections, but control of the patient was lost.

CASE V.—Lugo, Secondary syphilis, cutaneous (picture) Wassermann 3+ injections of 1/5 grain each. First treatment July 8; good results; skin clear on July 20; Aug. 3 periostitis of hands and limbs began to develop. During months of October and November patient was given 1/5 grain every four days. Occasional periosteal nodes would appear but subsided after the use of potassium iodide. Wassermann not made the second time; patient lost track of.

CASE VI.—Perez, Iritis, incipient paresis. Wassermann 4+. First dose caused pain in abdomen. Four injections of 1/6 grain; iritis was cured; mental symptoms and pain slightly alleviated.

CASE VII.—C. B., Leg ulcers, syphilitic, 3 inches in diameter. Wassermann 3+; nine injections of 1/6 grain. Left hospital before cured but legs were greatly improved.

CASE VIII.—F., U. S. Army retired: Leg ulcers both legs and gummata of both thighs. Wassermann +; four injections 1/5 grain. Ulcers healed considerably but left hospital before cured.

CASE IX.—Carrie W., Periostitis and syphilitic rheumatism. Wassermann ++. First dose caused diarrhea,

bloody stools and vomiting. Periostitis and rheumatism were relieved but patient discontinued the treatment just as soon as the immediate symptoms were alleviated.

CASE X.—D., Leg ulcers ow long standing. Wassermann +; three injections of 1/8 and seven of 1/6 grains. Ulcers healed.

CASE XI.—Julio, Adenitis of cervical glands; three doses of 606; Wassermann +; operated upon some years ago by Dr. P. for sarcoma of the neck glands. Five injections of 1/6 grain. Now practically well and selling papers upon the street.

CASE XII.—Mrs. M.—Twelve doses of venarsen; periostitis of the jaws and dropping out of the teeth. Three injections of 1/8 grain. Cured or more correctly relieved. These I think are the same kind of cases which have responded so favorably to the mercury salicylate and succinimide treatment of pyorrhea by White of the U. S. Navy.

CASE XIII.—Curtis, Hemiplegia of right side of six months duration. Wassermann positive; six doses of 1/6 grain. Practically cured when last seen.

CASE XIV.—John A., Arthritis and arthralgia; came in on crutches; seven doses of 1/6 grain. Cured; walked out without crutches.

CASE XV.—Wallace D., Ulcers and stricture of the rectum, fistulae and sinuses; greatly reduced weight and very anemic. First dose 1/6 grain. Marked salivation. Three or four doses of 1/8 grain. Patient gained in weight; greatly improved and ulcers healed.

CASE XVI.—Jno. K., Syphilitic heart and aortitis, broken compensation; came on stretcher; six doses of 1/5 grain. Greatly improved every way; left hospital in good condition and not seen since.

Conclusions.—(1) The intravenous usage of the bichloride of mercury is quick, safe, and certain; the dosage is mathematically exact and the administration is free from pain.

(2) The immediate introduction of the curative agent into the circulating blood is what has not been obtained by the other methods of using mercury.

(3) The phlebitis and the periphlebitis occur in proportion to the concentration of the solution used, and this danger can be minimized still further whenever the sensitiveness of the patient demands.

(4) The effects are just as quick, in many cases surer and more permanent than those following neosalvarsan or the salvarsan, and the drug acts in cases where these have given no appreciable results.

(5) Bichloride intravenously is the poor man's remedy, and, because of its cheapness, availability and ease of administration, I wonder why its use was ever discontinued after once it was thoroughly tried.

MOORE BUILDING

CLINICAL REPORT OF A FATAL CASE OF ANGINA PECTORIS.

By J. J. GINGLES, A.M., M.D., LL.D.,

SEATTLE, U. S. A.

FORMERLY PROFESSOR OF ANATOMY AND PROFESSOR OF CLINICAL SURGERY IN THE MEDICAL DEPARTMENT OF THE WILSON METTE UNIVERSITY, PORTLAND, ORE.

I WAS hurriedly summoned to the bedside of A. B., hotel proprietor, American, aged 64, early Monday morning, February 14, 1916. I found the patient in great agony, bathed in a cold perspiration, afraid to move, and suffering intensely from the pathognomonic pain of angina pectoris—following the full length of the intercosto-humeral nerve. The patient's face wore a look of despair, and he begged most piteously for relief.

I promptly administered a hypodermic injection of $\frac{3}{8}$ gr. morphine sulphate with 1/100 gr. atropine sulphate; had artificial heat applied over

seat of pain and to the lower extremities. After he was wholly relieved of pain, inquiry elicited the fact that he was a Christian Scientist, and that he had suffered from attacks of the same character, but of lesser severity, for some days prior to the morning he summoned me to attend him, and that the sufferer and his wife had employed Christian Scientist treatment for him during the interval of several days as above mentioned, without benefit, of course. He assured me he had endured all he could, and I believed him; he was extremely weak, well-nigh exhausted.

Further inquiry disclosed the existence of chronic catarrhal gastritis, which evidently had existed for a number of years, with occasional attacks of acute indigestion; each of these attacks being characterized by hyperacidity of the gastric fluid and consequent fermentation with overdistention of the stomach with gas. On this last occasion, the upward pressure upon the heart, evidently caused the angina pectoris.

The relief from pain was perfect and complete throughout the entire day (Monday) until about 8.00 P.M., when I was summoned again and in haste. I found him suffering in much the same manner, though less severely than in the morning. I again employed the same measures for his relief as in the morning, with the result of a complete night's rest and several hours of unbroken sleep.

This second attack had followed a light meal of bread and butter and some excellent home-made beef tea, and despite the exhibition of 30 gr. doses of sodium bicarbonate and two minim doses of beechwood creosote in solution, administered often.

Tuesday the treatment was continued, with very light diet, and in small amounts; the patient was quite comfortable until after his evening meal, when he was again the victim of a slight attack which was more readily controlled than on previous similar occasions. The patient again slept well all night.

Wednesday morning about an hour after the taking of one poached egg and one slice of buttered toast, the same overdistention of the stomach with gas and acid eructations occurred, accompanied yet again with angina as before. After once more relieving the intense pain, I ordered that he take no solid food, but instead he should depend entirely upon concentrated meat juice; and for treatment added a liquid digestive ferment to the creosote and soda bicarbonate.

The man was very fond of milk, and had been accustomed to using at least one quart daily; the milk was of the finest quality and stood a test of the most rigid form; but this patient, in common with other victims of excess of acid in the gastric juice and the inevitable fermentation, could not digest milk in any form, or in any amount; indeed his late illness doubtless resulted from his trying to live upon a milk diet alone.

Wednesday evening at 5.30, I gave him his second hypodermic injection for the day; waited until relief came, and then just at 6.00 P.M., I told the patient and his wife—who acted as his nurse, and did it well—that his hope of life and of recovery depended upon his keeping absolutely quiet; explaining that although he had no organic disease of the heart, no aneurysm, nor any arteriosclerosis, still his heart had grown extremely weak, and I most earnestly charged them, in view of the gravity of his condition, to keep him absolutely quiet, even furnishing them a catheter to be used if needed.

At 8.30, I was hastily summoned again, and arrived in time, a few minutes later, to see him gasp and die. His wife assured me he had felt no pain since my previous call at six, but that he had attempted to rise in order to urinate, and had fallen back on the pillow, saying, "I am so tired." I tried strychnine hypodermically, and overdilated both anal sphincters, all to no purpose. He was dead. Dilated heart.

In conclusion, I wish to state clearly that I submit this clinical report with the intent to make a true, unbiased statement of facts, my one and only motive being to emphasize the self-evident lessons therein.

To my mind, the most important lesson to be learned is this: The greatest harm that is done by irregular practitioners, by whatever name they are called, is that they, by their absurd pretense of cure, deprive the credulous victim of the precious time during which competent medical or surgical assistance, if secured, might relieve his suffering and in very many instances prolong the life of a fellow-being.

Medicolegal Notes.

Duty to Attend Patient—Effect of Impossibility to Do So.—In an action for malpractice it appeared that the patient had been treated for septicemia, which treatment was discontinued prior to the commencement of the action. The cause of action, if one existed, arose not out of improper treatment of that disease, but out of the defendant's negligence in failing to correctly diagnose the plaintiff's ailment as osteomyelitis. It was held to be immaterial what the result of the treatment would have been had it been continued, and equally immaterial what the correct treatment of osteomyelitis is.

It appeared that about the 12th of February, 1912, a condition arose in the affairs of the defendant whereby it was practically impossible for him to visit the plaintiff or to treat him during a considerable time thereafter, and that he instructed the plaintiff's father to continue the treatment, and to advise him promptly should any change occur for the worse; that no notice was given him of any change in the plaintiff's condition; that he was neither called upon to further treat his patient nor dismissed from the case; and that other physicians and surgeons were called about the 12th of March, 1912. The plaintiff requested an instruction that, if the jury found from the evidence that the defendant was employed to treat the plaintiff, and that he undertook to attend on him, the law presumes that such employment lasted during the sickness of plaintiff, and the relation of physician and patient continued between plaintiff and defendant until it was ended by the consent of the parties or revoked by the express dismissal of the defendant by the plaintiff. It was held that this instruction was properly refused. Assuming that it correctly stated a general principle of law, it had no proper application to the facts above recited, for it contemplated that no change had occurred in the affairs of the physician whereby he would be prevented from properly discharging his duties to his patient.—*Osborn v. Cary*, Idaho Supreme Court, 152 Pac. 473.

Unmuzzled Dogs—Regulation by New York City Board of Health.—Under the general provisions of the New York city charter prescribing the powers and duties of the board of health, and in view of various sections of the charter, from which it appears that the Legislature empowered such board to enact and enforce regulations and ordinances to protect and promote public health, in relation to many subjects over which the board of aldermen are given regulative power and control by the charter, and that the lawful regulations, ordinances, and orders of the board of health are paramount, Sanitary Code, § 80a, enacted by the board of health, providing that no unmuzzled dog shall be permitted to be on any public highway or in any public park or place, is valid as against an objection that the board of aldermen alone had power to enact such a regulation, notwithstanding the provisions of Greater New York Charter, §§ 50, 51, "that subject to the Constitution and laws * * * the board of aldermen shall have power to regulate the use of streets and sidewalks

by * * * animals * * *" and "shall have power to * * * regulate and forbid the keeping of dogs."—*People v. Warden*, New York Court of Appeals, 110 N. E. 451.

Tuberculosis Hospital Not a Nuisance.—A bill was filed by the city of Northfield, N. J., and several property holders, praying that the board of freeholders of Atlantic County be enjoined from erecting a hospital for the care of patients afflicted with pulmonary tuberculosis. "The evidence submitted," the court said, "does not justify the conclusion that any danger to health exists or can be reasonably apprehended from the operation of this institution, providing it is properly operated. In this view the only possible ground for relief is the claim that the establishment of the hospital is operative to materially reduce the market value of the adjacent real estate. That claim, standing alone, cannot justify the relief here sought. There are some authorities apparently to the contrary, but the weight of authority is clearly to the effect stated. A person cannot be denied the right to make a lawful use of his property merely because such use is operative to injure the market value of his neighbor's property; he will not be permitted to disturb the quiet enjoyment of his neighbor's habitation by interference with the atmosphere by unreasonable noises, odors, or gases; he will not be permitted to physically disturb his neighbor's property, as by backing water upon it or otherwise physically interfering with it; but the mere disturbance of market value is not regarded as an infringement of an existing right in the party damaged, and cannot be made the basis of relief of this nature." Preliminary injunction was denied.—*City of Northfield v. Board of Chosen Freeholders*, New Jersey Court of Chancery, 95 Atl. 745.

Medical Services as "Necessaries"—Wife Living Apart from Husband—Accouchement Case.—Medical services are necessities within the rule making the husband liable for necessities furnished to the wife, and when such services are necessary the husband cannot escape liability therefor by showing that he did not call in the physician, or even that the physician was called in against his consent, and over his objections.

If, however, through no fault of the husband, the wife abandons his home and refuses to live or cohabit with him, he is not responsible for her necessities, unless expressly requested by him; and persons furnishing her with such under such circumstances cannot, upon any theory of an implied request or of implied agency of the wife to bind the husband, collect from the husband.

And the mere fact that the wife is living apart from her husband is sufficient notice to the public who may deal with her, to put them on inquiry and to advise them that, so far as the liability of the husband is concerned, they credit the wife at their peril, since the law is that in cases of separation, the presumption is that the husband is not liable, placing the burden of proof on the party furnishing the necessities to show that the separation has taken place under such circumstances as will render the husband liable; that is, has taken place as the result of his cruelty, violence, abandonment, or other misconduct or fault on his part.

The case at bar was a suit by a physician against the husband for \$10 as the reasonable value of professional services rendered the wife during childbirth. It appeared that three and one-half months before the services were rendered the wife voluntarily abandoned the husband against his consent and without fault on his part, and had gone to live with her father, where she was when the child was born. The physician was called in over the telephone by someone at the house. It was not disputed that the services were necessary, that the amount sued for was reasonable, that the husband was the father of the child, or that the physician had not heard of the separation before he was called in. The sole insistence of the husband was that his wife had abandoned him over his objection and through no fault of his.

The plaintiff admitted that if the services had been solely for the wife's benefit the husband would not have been liable, but insisted that the services were equally as necessary to the preservation of the life of the defendant's offspring as of that of his wife, and that the defendant was liable, not on any theory of liability for services furnished his wife, who had abandoned him, but upon the theory of his liability for necessities furnished his child. It was held that the defendant was not liable, since a husband is not liable for the support of his minor children where his wife leaves him without cause, taking them with her.—*Johnson v. Coleman*, Alabama Court of Appeals, 69 So. 318.

NERVOUS CONTROL OF KIDNEY FUNCTION.

WHILE it is well known that the kidney is richly supplied with nerves, it has never been possible to demonstrate that this organ is furnished with any true secretory nervous fibers. It is unquestioned that section or stimulation of various nerves has marked effects upon the action of the kidney, but the readiness with which this organ responds to alterations in its blood supply has led most observers to the conclusion that the chief influence was carried through the vasomotor filaments and not through true secretory nerves.

Certain experiments have been carried out on the transplantation of this organ with results that would indicate that nervous control is not essential to its proper working, but not until very recently has any one done this work with a view of studying the function of the kidney under these conditions. Quinby (*Jour. Exper. Med.*, 1916, xxiii, 535) has adopted the technique of Carrel and others in this line and completely removed one kidney from the body and then sutured it back in place. A comparative study of the function of the two organs was undertaken when the animal had recovered from the effects of the operation. Quinby found that, at first, the reimplanted kidney showed more activity than the normal organ as measured by the output of both water and salt, but that later there was some return of control and both organs excreted practically equal amounts. The primary stimulation is accompanied by an engorgement of the kidney and is evidently due to the absence of vasomotor control such as is present in the normal kidney. For this reason the reimplanted organ does not suffer from the shock of operative procedures and begins to functionate as soon as the circulation is restored. In a second series of dogs the intact kidney was removed after the animal had recovered from the operation of reimplanting the opposite one. In these animals the renal function of the solitary reimplanted organ was apparently normal and it reacted normally to the injection of salt solution, lactose, and phenosulphone-phthalein. The blood urea remained at a normal level, so that there was apparently no nitrogen retention.

There is no possibility that, in these instances, the nervous connection of the kidney was not completely severed, and it seems highly improbable

that, in the short space of time after operation before the observations were made, nerve filaments could grow out and reestablish themselves in the kidney. These experiments, therefore, furnish very strong evidence that secretory nerves to the kidney do not exist. It is interesting to note that dogs having but a single kidney, and that one which had been subjected to reimplantation, were able to live normal lives for apparently an indefinite period. The author warns the reader that the operation must be done rapidly, for no kidney showed normal function after having been excluded from the circulation for longer than one hour and twenty minutes.

CARE OF THE FEEBLE-MINDED.

How best to care for the feeble-minded is a problem, the solution of which will tax the brains of medical authorities and legislators to the utmost. There are many mental defectives in every community who ought to be under restraint or cared for in such a way that they are not a menace to others. Probably from 10 to 20 per cent of those in prisons and reformatories are mentally defective. As was said in the Report of the New York Board of Charities, Feb. 15, 1915, the feeble-minded at liberty are a costly menace to the community, but under suitable custodial care they can be made useful and happy, and the danger of propagating their kind can be minimized. While it is allowed that mental defectives should be properly cared for, the question as to how this necessary and laudable object may be most effectively carried out is one that presents many difficulties.

Dr. Helen MacMurchy of Toronto, inspector of the feeble-minded in Ontario, has published recently her annual report, in which the subject of the mentally defective is dealt with ably and exhaustively. She outlines the kind of institutions which she thinks most economical and satisfactory as follows: (1) A sufficient population to admit of the economic unit in everything, and of good classification, say 1,000 to 2,000. These should be divided into comparatively small families, of about twelve to fifty in a family, each with special needs and characteristics, according to age, strength, sex, mental age, appearance, physical condition, ability, trainability, teachability, disposition, occupation, habits, manners, trustworthiness, etc. (2) Sufficient land, about one acre per inmate, for an Industrial Plan Colony. (3) Simple buildings on the cottage system, costing about \$400 per bed and built by the inmates as far as possible. (4) Workshops and industries, farm and garden work and training and suitable equipment so that the institution may be self-supporting and self-contained, producing and manufacturing all that the inmates need. (5) The best superintendent that can be procured. (6) A staff of officers of the highest type, well organized and comfortably and suitably provided with residence, recreation, and opportunities for improvement in their work and development of their talents in every direction.

It is obvious that education and bringing up will exert a considerable amount of influence upon the future of mental defectives, and it seems almost

as obvious that an institution of the type sketched by Dr. MacMurchy will most fittingly fulfill the purpose. Those who are diagnosed as mentally defective should be trained so as to be self-supporting as far as it is possible, but should not be allowed enough liberty to be a source of danger to the community. It appears wholly against the best interests of the race, nation, and community that a person mentally defective should be permitted to perpetuate the species, and one who is palpably deficient in intelligence should be kept under restraint. The most dangerous of the large army of mental defectives are those who are weak-minded but not sufficiently so to be restricted as to liberty. These spread vice and disease on all hands and help to fill our prisons and reformatories. At any rate, steps should be taken to diagnose mental deficiency, and when a diagnosis has been made, to have all suffering from such defects intelligently and kindly treated according to their grades of deficiency, but always bearing in mind that the welfare of the race at large must come first, and that for the good of the same majority the abnormal members of society must be restricted in their harmful activities.

CHRONIC TETANUS.

TETANUS has shown several phases in which prolonged time is a characteristic. There is the so-called latent form, in which a missed infection is awakened to activity weeks or months after the infliction of the wound. A case of tetanus relapse has been or will be reported from the Halle Clinic in Germany. These phases of tetanus are so rare as to be almost unique, while in theory another condition might occur, to wit, chronic tetanus in the legitimate sense of the word. Cases of chronic tetanus, so-called, in which the duration of the disease is unduly prolonged should be termed subacute at best. An actual case of chronic tetanus lasting over seven months was reported by Faust at a medical meeting held at Dresden (*Muenchener medizinische Wochenschrift*, January 18). The author made an extensive research into literature, and so far as he knows, his case is quite unique. The man made an incomplete recovery, his jaws were still partly locked, and other muscles were in a hypertonic state. The original injury was a shell fragment wound of the left foot, which was properly dressed. Ten days later the muscular rigidity was noted and antitoxin injected. Meanwhile the wound was healing well and no fever had developed. Trismus was marked, and there were several convulsions daily, due to internal irritation. Aside from these the muscular state was one of rigidity, the patient feeling rheumatic. Everything was done to relax the muscles, but to no purpose. After 136 days the rigidity began to give way spontaneously, so that the patient could leave his bed and get about. Lockjaw and abdominal rigidity persisted. A study of the case in detail shows that on the 78th day the muscles began to relax, but soon afterward the disease returned in full strength, with fresh and violent convulsions. There is no mention of the date of the last attack.

Old authorities have mentioned a so-called rheu-

matic tetanus, entirely benign in character and without history or evidence of an entrance wound. The author does not allude to this condition, which goes back to the prebacteriological era; but a comparison of it with his own case would have seemed worth while.

HINDHEDE ON DIET.

THE views of Hindhede, the Danish dietician, are but slightly known to the American medical public and it is only quite recently that his little works on nutrition and cookery have been translated into German. As an advocate of what many of his colleagues would call underfeeding, these translations are timely for Germany and might be equally so for other warring nations. His ideal regimen is milk, bread, potatoes, and fruit, but he realizes that this ideal is unattainable. Concerning meat he says harsher things, if possible, than the avowed vegetarians themselves, for he attributes to its overconsumption almost all imaginable evils; yet many of his dietaries contain small quantities of flesh foods. When it comes to the possible protein minimum requirement he makes Chittenden and Fletcher appear conservative in comparison. He resembles the latter in the economical side of dietetics and computes the low cost of a satisfactory ration. From this angle he likens meat to chocolate bonbons. His German book reviewers do not mention caloric requirements, but lay stress on tables showing uric-acid formers, and basic-salt formers. Hindhede writes down to the lay reader whom he evidently means to reach. For twenty years he has been studying practical dietetics among the peasants of Jutland. He indirectly attacks much of the teachings of his German confrère or rival, Rubner, and the latter, who is regarded by his countrymen as the world's greatest authority on dietetics, will surely reply to him. Needless to say, such a document will be of considerable interest to those, and their name is legion, who are making a careful study of food value and nutrition.
